The blind mind: No sensory imagery in aphantasia

Rebecca Keogh & Joel Pearson

University of New South Wales
Abstract

For most people the use of visual imagery is pervasive in daily life, but for a small group of people the experience of visual imagery is entirely unknown. Research based on subjective phenomenology indicates that otherwise healthy people can completely lack the experience of visual imagery, a condition now referred to as aphantasia. As aphantasia has thus far been based on subjective reports, it remains unclear whether participants are really unable to imagine visually, or if they have very poor metacognition; that is they have images in their mind, but are blind to them. Here we measured subjectively diagnosed aphantasic’s sensory imagery, using the binocular rivalry paradigm, as well as measuring their self-rated object and spatial imagery with multiple questionnaires (VVIQ, SUIS and OSIQ). Unlike, the general population, experimentally naive aphantasics showed almost no imagery-based rivalry priming. Aphantasic participant’s self-rated visual object imagery was also well below average, however their spatial imagery scores were above average. These data suggest that aphantasia is a condition involving a lack of sensory and phenomenal imagery, and not a lack of metacognition. The possible underlying neurological cause of aphantasia is discussed as well as future research directions.
‘What does a person mean when he closes his eyes or ears (figuratively speaking) and says, “I see the house where I was born, the trundle bed in my mother’s room where I used to sleep – I can even see my mother as she comes to tuck me in and I can even hear her voice as she softly says goodnight”? Touching, of course, but sheer bunk. We are merely dramatizing. The behaviourist finds no proof in imagery in all this. We have put these things in words long, long ago and we constantly rehearse those scenes verbally whenever the occasion arises’ ~ John B Watson

The study of visual imagery has been a controversial topic for many years, as the above quote from the behaviourist John Watson demonstrates. This quote exemplifies the long running imagery debate of the 1970s and 80’s, which centred on the question of whether imagery can be depictive in the format of its representation (Kosslyn, 2005), or only symbolic or propositional in nature (Pylyshyn, 2003). However, in the last few decades psychologists and neuroscientists have made great strides in showing that visual imagery can be measured objectively and reliably, and indeed can be depictive or pictorial in nature (Pearson & Kosslyn, 2015). Additionally, visual imagery has been shown to be closely related to a myriad of cognitive functions such as visual memory (Albers, Kok, Toni, Dijkerman, & de Lange, 2013; Keogh & Pearson, 2011, 2014), spatial navigation (Ghaem et al., 1997), language comprehension (Bergen, Lindsay, Matlock, & Narayanan, 2007; Zwaan, Stanfield, & Yaxley, 2002) and making moral decisions and intentions to help (Amit & Greene, 2012; Gaesser & Schacter, 2014). Visual imagery also appears to be elevated in some psychological and neurological disorders (Matthews, Collins, Thakkar, & Park, 2014; Sack, van de Ven, Etschenberg, Schatz, & Linden, 2005; Shine et al., 2015). Visual imagery has even been employed to assist in cognitive behavioural therapies such as imaginal exposure (Holmes, Arntz, & Smucker, 2007; Pearson, Naselaris, Holmes, & Kosslyn, 2015).
With strong evidence that visual imagery can be a depictive cognitive mechanism, the question arises, were Watson, Pylyshyn and their ilk wrong? Or is it possible that they had a distinctly different experience of visual imagery that was not depictive, but more propositional or phonological in nature? Interestingly, a study investigated exactly this idea and found that those researchers who were more likely to have been on the ‘imagery is depictive’ side of the debate tended to report more vivid imagery, while those who reported weaker imagery were more likely to be on the imagery is propositional side of the debate (Reisberg, Pearson, & Kosslyn, 2003). One of the hallmarks of visual imagery is the large range of subjective reports in the vividness of an individual’s imagery. For example, when people are asked to imagine the face of a close friend or relative some people report imagery so strong it is almost akin to seeing that person, whereas others report their imagery as so poor that, although they know they are thinking about the person, there is no visual image at all. Sir Francis Galton gave one of the earliest accounts of these subjective differences in visual imagery in 1883. Galton devised a series of questionnaires asking participants to imagine a specific object then describe the ‘illumination’, ‘definition’ and ‘colouring’ of the image. He found, to his surprise, that many of his fellow scientists professed to experience no visual images in their mind at all: ‘To my astonishment, I found that the great majority of the men of science to whom I first applied protested that mental imagery was unknown to them, and they, looked on me as fanciful and fantastic in supposing that the words “mental imagery” really expressed what I believed everybody supposed them to mean. They had no more notion of its true nature than a colour-blind man, who has not discerned his defect, has of the nature of colour. They had a mental deficiency of
which they were unaware, and naturally enough supposed that those who
affirmed they possessed it, were romancing." In recent years very little attention
has been given to the 'poor' or non-existent side of the visual imagery spectrum,
outside of participants with neurological damage. Much research during the
imagery debate of the 70's and 80's revolved around brain damaged participants
who had lost their ability to imagine, but retained their vision, or vice versa, in an
attempt to understand the neural correlates of visual imagery (Farah, 1988).
Recently the idea that some people are wholly unable to create visual images in
mind, without any sort of neurological damage, psychiatric or psychological
disorders, has seen a resurgence. A recent paper by Zeman et al., (2015) coined
this phenomenon as 'congenital aphantasia'. This study found that these self-
described aphantasics all scored very low on the vividness of visual imagery
questionnaire (VVIQ), which is a commonly used questionnaire to measure the
subjective vividness of an individual's visual imagery, by asking them to imagine
scenes and rate the vividness on a Likert scale. However, a case study reported a
gentleman who became aphantasic after surgery (without any obvious
neurological damage) and was still able to perform well on other measures of
visual imagery, such as answering questions about the shape of animal's tails.
The patient was also able to perform a mental rotation task, another commonly
used test of imagery ability (Zeman et al., 2010). Interestingly, his reaction times
however, did not correspond to the rotation distance, which is the common
finding in the literature. These reports suggest the possibility that aphantasic
individuals do actually create images in mind that they are able to use to solve
these tasks, however they are unaware of these images; that is they lack
metacognition, or an inability to introspect.
Although the visual imagery tasks used in the Zeman et al., (2010) study are used extensively throughout the imagery literature, and in clinical settings to measure visual imagery, the validity of these tasks are somewhat unclear. For example, in the animal tails test it may be that subjects can use propositional semantic information about the images they are asked to imagine, instead of actually creating a visual image in mind. Additionally, the mental rotation task used (mannikin test) could be performed using spatial, or kinaesthetic imagery, rather than 'low-level' visual object imagery. A relatively new experimental imagery task, which exploits a visual illusion known as binocular rivalry, allows us to eliminate many of the issues related to these visual imagery measures (Pearson, 2014). Binocular rivalry is an illusion, or process, where one image is presented to the left eye and a different image to the right, which results in one of the images becoming dominant while the other is suppressed outside of awareness (see figure 1A for illustration). Previous work has demonstrated that presenting a very weak visual image of one of the rivalry patterns prior to the presentation of the binocular rivalry display, results in a higher probability of that image being seen in the subsequent binocular rivalry presentation (Brascamp, Knapen, Kanai, van Ee, & van den Berg, 2007; Pearson, Clifford, & Tong, 2008). Interestingly, when someone imagines an image instead of being presented with a weak one, a very similar pattern of results emerges. In other words, imagery can prime subsequent rivalry dominance much like weak visual perception (Pearson, 2014; Pearson et al., 2008). Hence, this imagery paradigm has been referred to as a measure of the sensory strength of imagery, as it bypasses the need for any self-reports and directly measures sensory priming from the mental image.
If an individual is presented with a uniform and passive luminous background while they imagine, the facilitative effect of their mental image is reduced (Chang, Lewis, & Pearson, 2013; Keogh & Pearson, 2011, 2014; Sherwood & Pearson, 2010), suggesting that the early visual areas of the brain are crucial for the construction and maintenance of these images. Additionally, this priming effect is local in both retinotopic spatial-locations and orientation feature space (Bergmann, Genc, Kohler, Singer, & Pearson, 2015; Pearson et al., 2008), further suggesting the priming is contingent on early visual processes.

This measure of visual imagery also correlates with subjective ratings of visual imagery, both trial-by-trial and questionnaire ratings, suggesting that participants have insight into the strength of their own visual imagery (Bergmann et al., 2015; Rademaker & Pearson, 2012). Here we ran a group of self-described congenital aphantasics on the binocular rivalry visual imagery paradigm to measure the strength of their sensory imagery. If congenital aphantasia is a complete lack of visual imagery, we should expect no facilitative priming effects of visual imagery on subsequent rivalry. However, if congenital aphantasia is instead a lack of metacognition, or failed introspection, then we may expect to observe some priming, despite the subjective reports of no imagery. We further, tested the aphantasics on a range of standard questionnaires to probe the vividness and spatial qualities of their imagery.
Methods and Materials

Participants

Fifteen (aged 21-68, 7 female) self-described aphantasic participants completed all experiments and questionnaires. The Aphantasics were recruited through a Facebook page, had emailed the lab regarding their aphantasia or were referred to us through Adam Zeman. The control, or ‘general population’ group uses data that was collected over numerous experiments, some of which were published in a number of different journal articles (see: (Keogh & Pearson, 2011, 2014; Shine et al., 2015) while some are as yet unpublished, all using the same binocular rivalry visual imagery task, with the exact same stimulus and instructions, however not all of the studies included vividness ratings; the sample contains 209 different individuals. The age range of these 209 participants is from young adult (18 years +) to elderly (80’s).

Fifteen control participants also completed the OSIQ (age range 18-35, 10 female).

All experiments were approved by the UNSW psychology ethics committee.

Stimuli

All participants (in the aphantasic and general population) were tested in blackened rooms with the lights off, and their viewing distance from the monitor was 57cm and was fixed with the use of a chin rest. The data for the general population were collected over several years and used several different
computer monitors and testing rooms, as such the stimuli parameters will all be slightly different, due to monitor and graphics card differences. However, all the experiments were performed by the same experimenter (RK), who ran all participants in the aphantasia and general population studies. The following specific stimuli parameters described, are for the aphantasic participants of this study.

In the imagery task the binocular rivalry stimuli consisted of red horizontal (CIE x = .57, y = .36) and green vertical (CIE x = .28, y = .63) Gabor patterns, 1 cycle/°, Gaussian $\sigma = 1.5^\circ$. The patterns were presented in an annulus around the fixation point and both Gabor patterns had a mean luminance of 4.41 cd/m². The background was black throughout the entire task during the no luminance condition. For the imagery luminance condition the background ramped up to yellow (a mix of the green and red colours used for the rivalry patterns, with luminance at 4.41 cd/m²), during the six-second imagery period. During this period the background luminance was smoothly ramped up and down to avoid visual transients, which may result in attention being directed away from the task.

Mock rivalry displays were included on 12.5% of trials to assess any effects of decisional bias in the imagery task. One half of the mock rivalry stimulus was a red Gabor patch, with the other half being a green Gabor patch (a spatial mix) and they shared the same parameters as the green and red Gabor patches mentioned in the previous paragraph. The mock rivalry stimuli were spatially split with blurred edges and the exact division-path differed on each catch trial (random walk zig-zag edge) to resemble actual piecemeal rivalry.
**Experimental Procedure**

All aphantasic participants came to the university of new south wales to participate in approximately 3 hours of testing. They were reimbursed $15 AUD per hour for their participation in the study. At the beginning of the experimental session they were briefed verbally about the study and written informed consent was obtained. The participants then completed the following questionnaires and binocular rivalry task (lasting for about 1 – 1.5 hours) as well as completing some other memory and imagery tasks for a different study, not reported on here.

**Questionnaires**

All participants completed the vividness of visual imagery questionnaire (VVIQ2) (Marks, 1973), spontaneous use of imagery scale (SUIS) (Reisberg, Culver, Heuer, & Fischman, 1986), and the object and spatial imagery questionnaire (OSIQ) (Blajenkova, Kozhevnikov, & Motes, 2006). The VVIQ asks participants to imagine several scenes and then rate how vivid their imagery is for each item on a scale of 1-5; with 1 = ‘No image at all, you only "know" that you are thinking of the object’ and 5 = 'Perfectly clear and vivid as normal vision'. Both the SUIS and the OSIQ give participants statements and they have to rate how much they agree with the statement from 1-5, with 1 = ‘totally disagree’ and 5 = ‘totally agree’. An example question from the SUIS is: 'When I hear a radio announcer or DJ I've never actually seen, I usually find myself picturing what they might look like'. 
**Binocular rivalry task**

Before completing the binocular rivalry imagery task each participant’s eye dominance was assessed (for a more in depth explanation see [Pearson et al., 2008](#)) to ensure rivalry dominance was not being driven by pre-existing eye dominance, as this would prevent imagery affecting rivalry dominance.

Following the eye dominance task participants completed either 2 or 3 blocks of 40 trials depending on time constraints and number of mixed precepts. Mixed precept trials were not analysed here, so for this reason we attempted to have at least 60 analysable trials per participant, however due to time constraints and mixes, 4 participants only completed 32, 34, 35, and 45 trials. There was however no correlation between the number of trials completed and rivalry priming ($r_s = .04$, $p = .90$, Spearman’s correction for non-normality), hence these participants’ data are included in the analysis. Participants also completed 2 or 3 blocks of 40 trials of the binocular rivalry task with a luminous background during the imagery period.

*Binocular rivalry imagery paradigm:* Figure 1B shows the timeline of the binocular rivalry imagery experiment. At the beginning of each trial participants were presented with either an ‘R’ or a ‘G’ which cued them to imagine either a red-horizontal Gabor patch (‘R’) or a green-vertical Gabor patch (‘G’). Following this, participants were presented with an imagery period of six seconds. In the no luminance condition the background remained black during this imagery period, in the luminance condition the background ramped up and down to yellow over the first and last second of the 6s imagery period to avoid visual transients. After this six second period participants were asked to rate how ‘vivid’ the image they imagined was on a scale of 1-4 (using their left hand
on the numbers on the top of the keyboard) with ‘1’ = ‘No image at all, you only “know” that you are thinking of the object’ and ‘4’ = ‘Perfectly vivid’. After this they were presented with a binocular rivalry display comprising the red-horizontal and green-vertical Gabor patches and asked to indicate which image they saw most of, using their right hand on the key pad: ‘1’ = green-vertical, ‘2’ = perfectly mixed, ‘3’ = red-horizontal.

Figure 1. Binocular rivalry and experimental timeline. A. Illustration of an extended binocular rivalry presentation. Two separate images are presented, one to each eye, instead of seeing a mix of the two, perception fluctuates between the two images. Fluctuations only occur for prolonged viewing, not for our brief rivalry presentation. B. Binocular rivalry experimental timeline. Participants were cued to imagine one of two images (r = red-horizontal Gabor patch and g = green-vertical Gabor patch). Participants imagined this image for six seconds, then after six seconds they rated how vivid the image they created was on a scale of 1-4. After this they were presented with a very brief binocular rivalry display (750ms) and had to report which colour they saw.
Results

Table 1 and figure 2A-C show participants’ scores on the visual imagery questionnaires. The data supports Zeman et al, (2015) findings that aphantasic participants rate their imagery as very poor or non-existent on the VVIQ. These data also show that participants also rate their spontaneous use of visual imagery as very low on both the SUIS and Object component of the OSIQ. Interestingly, the aphantasic participants’ spatial component of the OSIQ was almost double that of their object score. To further assess this finding 15 non-age matched participants also completed the OSIQ. There was a significant interaction between the spatial and object components of the OSIQ and the participant group (aphantasic/control), F(1, 28) = 45.25, p < .001 (see figure 2D). As expected the aphantasic participants rated their use of spontaneous object imagery as significantly lower than the controls (p < .001). The aphantasics self-rated spontaneous use of spatial imagery was not significantly higher than the controls (P=.15), mean scores: Aphantasic = 41.8 and control = 36.53.

Next the binocular rivalry imagery priming scores were examined. As can be seen in figures 1E and F, aphantasics had significantly lower priming on average than our general sample of participants (Mann-Whitney U = 914, \( p < .01 \), 2-tailed). In fact, the aphantasic group's priming scores were not significantly different from chance (50%) (figure 1E grey filled bar, \( t(14) = .68, p = .51 \)), unlike the general population whose mean is significantly different to chance (\( t(208) = 10.96, p < .001 \)). There were also no correlations between visual imagery priming for the aphantasic participants and any of the questionnaire measures, likely due to a restriction of range (all \( p's > .37 \)). Additionally, when aphantasic participants completed the task with a luminous background during the imagery period, their priming was no different to priming in the no luminance condition (\( t(14) = 1.10, p = .29 \)) and was again not significantly different from chance (\( t(14) = 1.75, p = .10 \)). These results suggest that the aphantasic participant's imagery has little effect on subsequent binocular rivalry. Aphantasic participants' mean 'online' trial-by-trial vividness ratings were also very low, with the average ratings not significantly different from the lowest rating of 1 (no luminance condition: \( t(14) = 1.18, p = .36 \), luminance condition: \( 1.37, p = .19 \), see figure 2G). The vividness ratings were not different between the no luminance and luminance conditions (\( t(14) = 1.10, p = .29 \)).
Figure 2. Frequency Histograms for aphantasic participants scores on the VVIQ (A), SUIS (B) and Object components of the OSIQ (C). D. Object and spatial scores on the OSIQ for aphantasic (white bars) and control participants (grey bars). E. Frequency histogram for imagery priming scores for aphantasic participants (yellow bars and orange line) and general population (grey bars and black dashed line). F. Average priming scores for aphantasic participants in the no background luminance condition (dark grey bar), aphantasic participants in the background luminance condition (white bar) and general population (light grey bar). G. Mean 'online' trial-by-trial vividness ratings for aphantasic participants in the no background luminance (grey bars) and luminous background condition (white bar). H. Frequency histogram of Bootstrapping from the general population data. 15 subjects were randomly chosen, averaged, then returned to the main pool of subjects. Data shows the distribution of the mean of N=15 for 1000 iterations. The aphantasic mean is shown on the far left (orange dotted line), with a P = .001 chance of pulling such a mean from the general population. All error bars show ±SEM’s

Our aphantasic group sample size was very small compared to our general population sample (15 vs 209). Hence, we wanted to ensure our results were not spurious, due to the small sample size. To further assess this we ran a bootstrapping resampling analysis to ascertain the probability of getting the aphantasic mean priming score by randomly sampling from the general population. To do this we pulled a random fifteen participants out of our general pool of participants and recorded the group mean priming score, this was done
1000 times, the results of this resampling can be seen in figure 2H. We found that of the 1000 iterations only one had an average score equal to or less that the mean priming score of the aphantasic participants, or a probability of $p = .001$. These results suggest that it is highly unlikely (1 out of a 1000) that our result is a spurious one due to random chance or our small sample size.

**Discussion**

Our combined findings from the imagery questionnaires and psychophysical imagery task support the theory that congenital aphantasia is characterised by a lack of low-level sensory visual imagery, and is not due to a lack of metacognition or an inability to introspect. So why is it that some people appear to be born without visual imagery?

An interesting finding from our results is that while the aphantasic participants were impaired on all measures of visual object imagery (lower VVIQ, SUIS, Object OSIQ and imagery priming scores), they were not impaired on their spontaneous use of *spatial* imagery, in fact on average they rated their spontaneous use of spatial imagery higher than a control group (although this effect was not significant). This measure of spatial imagery has been shown to correlate with performance on mental rotation tasks (Blajenkova et al., 2006). Interestingly, a case study by Zeman et al., (2010) found that their patient who developed aphantasia after surgery was still able to perform perfectly on a mental rotation task. The ‘what’ and ‘where’ pathways of the visual processing stream may help explain these findings. The dorsal (early visual cortex to parietal lobes), or ‘where’ stream contains information about the location of
objects in space, while the ventral (early visual cortex to temporal lobe) or ‘what’ stream contains information about an object’s identity, which becomes more and more complex as it moves up the hierarchy (Goodale & Milner, 1992).

Neuroimaging and brain stimulation work has demonstrated that mental rotation activates the where pathway (specifically the parietal cortex) (Harris & Miniussi, 2003; Jordan, Heinze, Lutz, Kanowski, & Jancke, 2001; Parsons, 2003; Zacks, 2008), in addition to the motor areas such as the supplementary motor areas and primary motor cortex (Cona, Marino, & Semenza, 2016; Ganis, Keenan, Kosslyn, & Pascual-Leone, 2000; Kosslyn, DiGirolamo, Thompson, & Alpert, 1998). In contrast to this, when participants imagine static images the visual cortex tends to show increased activity (Cui, Jeter, Yang, Montague, & Eagleman, 2007; Kosslyn, Alpert, & Thompson, 1997; Kosslyn & Thompson, 2003) and when individuals imagine simple Gabor patches the content of the image can be decoded from early visual cortex (Albers et al., 2013; Koenig-Robert & Pearson, 2016). Another study has shown that the level of BOLD response in the visual cortex during an imagery task correlates with the subjective vividness of an individual’s visual imagery (Cui et al., 2007). These results suggest a separation in the neural networks used in static object imagery and mental rotation or spatial imagery; as such it may be the case that aphantasics may have a severe deficiency with the ventral or ‘what’ pathway, or components of the pathway such as early visual or temporal cortex, but not the where pathway.

Research has indicated that when people imagine visual scenes or objects not just the visual cortex is activated, but also a large network extending to the parietal and frontal areas (see (Pearson et al., 2015). It is thought that the frontal engagement is driving feedback connections that activate the sensory
representations in the visual cortex. It may be possible that aphantasics have a
deficit with these feedback connections from frontal cortex, and are unable to
activate the visual cortex in such a way as to create a visual image in mind.

Recent work from our lab indicates that cortical excitability of both the visual
and pre-frontal cortex plays an important role in governing imagery strength
(Keogh, Bergmann, & Pearson, 2016), hence it may be that aphantasics have
abnormal activity levels in either the visual, frontal or both areas.

Further research should investigate exactly what other behavioural and
cognitive functions are impaired or even boosted in aphantasics. Additionally,
functional neuroimaging research will be important for identifying possible
differences in regional cortical activity during imagery based tasks as well as the
large scale neuronal networks that may differ in aphantasics compared to the
general population. This research will not only help to improve our
understanding of the mechanisms of visual imagery, but will help us to
understand the neurological differences that give rise to our vastly different
abilities and experiences of our internal worlds.

Acknowledgements: We would like to thank first of all of our aphantasic
participants who participated in the research. We would also like to give a
special thanks to Adam Zeman for his generous time and putting us in touch with
many of the participants in this study.
