Are Happier People More Compliant?

Global Evidence From Three Large-Scale Surveys During Covid-19 Lockdowns ¹

¹ We thank Pierce Gately, Marta Golin, Caspar Kaiser, Claryn Kung, Richard Layard, Lucia Macchia, Andrew Oswald, Nattavudh Powdthavee, Alberto Prati, Christopher Wratil, Katya Pinchuk, and seminar participants at the LSE Covid-19 Behavioural Science and Oxford Wellbeing Research Centre seminar series for helpful comments and suggestions. We are grateful to Pierce Gately and Ekaterina Oparina for excellent research assistance. We thank the Gallup Organization for providing access to the Gallup World Poll as well as the University College London Covid-19 Social Study and the Imperial College London-YouGov Behavioural Tracker team for providing access to their respective datasets. We thank Sarah P. Jones, Melanie Leis, and Roberto Fernandez Crespo (Imperial College London Institute of Global Health Innovation) and Gavin Ellison and Marcus Roberts (YouGov) for their role in survey concept and design, data collection and preparation, and for clarifying the methodology that was used for the Imperial College London-YouGov Behavioural Tracker. The University College London Covid-19 Social Study was funded by the Nuffield Foundation [WEL/FR-000022583], but the views expressed are those of the authors and not necessarily the Foundation. The study was also supported by the MARCH Mental Health Network funded by the Cross-Disciplinary Mental Health Network Plus initiative supported by UK Research and Innovation [ES/S002588/1], and by the Wellcome Trust [221400/Z/20/Z]. Daisy Fancourt was funded by the Wellcome Trust [205407/Z/16/Z]. The researchers are grateful for the support of a number of organisations with their recruitment efforts including: the UKRI Mental Health Networks, Find Out Now, UCL BioResource, HealthWise Wales, SEO Works, FieldworkHub, and Optimal Workshop. The funders had no final role in the study design; in the collection, analysis and interpretation of data; in the writing of the report; or in the decision to submit the paper for publication.

Abstract

Around the world, governments have been asking their citizens to substantially change their behaviour for a prolonged period of time, by practising physical distancing and staying at home, to contain the spread of Covid-19. Are happier people more willing to comply with these measures? Using three independent surveys covering about 119,000 adult respondents across 35 countries, including longitudinal data from the UK, we found that past and present happiness predicts compliance during lockdown. The relationship is stronger for those with higher levels of happiness. A negative mood, or loss in happiness, predicts lower compliance. We explored risk-avoidance and pro-social motivations for this relationship, and found that motivations for compliance are not uniformly distributed but dependent on personal characteristics and context: people who are older or have certain medical preconditions seem to be predominantly motivated by risk-avoidance, whereas motivations of people who are less at risk of Covid-19 seem more mixed. Our findings have implications for policy design, targeting, and communication.

Introduction

There is growing evidence on the predictive power of subjective wellbeing, hereafter referred to as *happiness*, for subsequent behaviour. For instance, people who are happier have been shown to be more productive (De Neve and Oswald, 2012; Oswald et al., 2015), to live longer (Danner et al., 2001; Diener and Chan, 2011; Steptoe and Wardle, 2011; Graham and Pinto, 2019), and to be more likely to vote for an incumbent, an effect that holds even after accounting for economic factors (Liberini et al., 2017; Ward, 2020; Ward et al., 2020).

We contribute to this growing literature by studying whether happiness predicts civic compliance, defined as a sustained change in the behaviour of an individual choosing to adhere to the recommendations of an authority. In particular, we looked at the unique setting of Covid-19 lockdowns, in which governments around the world have been asking their citizens to substantially change their behaviour for a prolonged period of time, by practising physical distancing and staying at home, to contain the pandemic. Are happier people more willing to comply with these measures?

The answer to this question is not *ex-ante* clear, for two reasons. First, it is not entirely clear what, in the current situation, motivates civic compliance. Motivations could range from risk-avoidance (avoiding health risk to oneself or to one's family and friends, or avoiding legal risk from not complying with recommendations) to pro-social behaviour (helping unknown third parties or the system as a whole), amongst others. Although non-compliance entails personal risks, many governments appealed to individuals' pro-sociality. For example, during most of the UK lockdown, the government's appeal was "Stay at Home, Protect the NHS [National Health Service], Save Lives", which is a pro-social appeal in a loss aversion framing. What is more, these motivations may vary, and may vary even within the same individual over time.

Second, two dominant psychological theories make contradictory predictions about the effect of happiness on civic compliance, regardless of whether the underlying motivation is

risk-avoidance or pro-social behaviour. The *affect infusion model* (Forgas, 1995) predicts that happier people show less civic compliance, because positive affect makes people perceive risky prospects more favourably (in case of risk-avoidance) or because it creates more internally oriented mental processing that promotes selfishness (in case of pro-social behaviour) (Tan and Forgas, 2010; Forgas and Tan, 2013). On the contrary, the *mood maintenance model* (Isen and Patrick, 1983) predicts that happier people show more civic compliance in case of risk avoidance, as positive affect makes people more loss averse (Johnston and Tversky, 1983). This is in line with classic economic expected utility theory: people who have a higher marginal utility of life (put simply, who enjoy life more) have more to lose, cf. Goudie et al. (2014). In case of pro-sociality, predictions can go either way: happier people may show more compliance if compliance promotes their self-image, makes them appear more favourable in social comparisons, and promotes good feelings more generally. However, people may show less compliance if complying becomes too unpleasant (Carlson et al., 1988). Table 1 summarises the different theoretical predictions.

[Table 1 about here]

We exploited Covid-19 lockdowns as a large-scale, quasi-natural experiment to test these contradictory predictions, studying whether past and present happiness predicts civic compliance, both observed and self-reported, both between and within countries. Covid-19 lockdowns yield ideal experimental conditions: they require a homogeneous set of behaviours for a limited amount of time from almost everybody in the population, with few exceptions. However, people differ substantially in terms of health consequences when catching the virus: the case-fatality ratio increases exponentially from age 60 onwards (Levin et al., 2020; Verity et al., 2020), and there is evidence that people with certain medical preconditions – high blood pressure, diabetes, and heart and lung disease – are at particular risk (Chen et al., 2020; Fang

et al., 2020). We exploited these age and health gradients to study underlying motivations for behaviour.

Using nationally representative cross-section data on about 50,000 respondents from 892 regions in 49 countries from the Gallup World Poll, in Study 1, we first looked at whether past and present regional happiness predicts observed regional compliance behaviour during lockdowns. In particular, we ran a cross-country analysis, studying whether regions that reported higher levels of happiness in 2019 showed higher levels of compliance during subsequent lockdowns in 2020. We measured compliance objectively, using changes in geographical mobility, measured by Google smartphone recorded visits to (or time spent in) various areas such as retail, parks, and residential.

In Study 2, we looked at whether present individual happiness predicts self-reported individual compliance behaviour in various domains during lockdowns. Here, we used cross-section data on about 39,000 respondents from 330 regions in 20 countries from the Imperial College London-YouGov Covid-19 Behavioural Tracker.

In Study 3, we focused on lockdown in a single country – the UK – exploiting a novel panel of more than 30,000 individuals – the University College London Covid-19 Social Survey – which started just before lockdown began (March 23) and includes weekly data on participants across the entire 'strict' lockdown period (March 23 to May 10, 2020). We applied individual fixed effects and dynamic panel data models to look at how present individual happiness predicts self-reported individual compliance longitudinally within individuals. We further exploited age and health gradients of respondents to study motivations underlying compliance behaviour.

Throughout these studies, our primary outcome was life evaluation or satisfaction, which is a cognitive, evaluative component of subjective wellbeing (or happiness) (Diener et al., 2002). However, we also looked at alternative components (such as how worthwhile things in life feel, or positive and negative affect) whenever feasible.

Our paper contributes to a steadily growing stream of literature on the determinants of compliance behaviour during Covid-19 lockdowns, including, amongst others, socio-demographic factors (Brough et al., 2020; Brown and Ravallion, 2020; Papageorge et al., 2020), beliefs and expectations (Akeson et al., 2020; Briscese et al., 2020; Kozlowski et al., 2020), trust and social capital (Bargain and Aminjonov, 2020; Bartscher et al., 2020; Brodeur et al., 2020), and political partisanship (Alcott et al., 2020; Golstein and Wiedemann, 2020; Simonov et al., 2020), and the type of state and local policies, for example state-of-emergency declarations, stay-at-home restrictions, or industry-specific restrictions (Cronin and Evans, 2020). Here, the authors found that private, self-regulating behaviour explained more than three-quarters of the decline in foot traffic in most industries. By pointing towards the potentially mediating role of happiness for risk-taking and compliance, our paper may help reconcile emerging contradictory evidence on risk-avoidance and compliance, in particular that perceived personal health risks associated with Covid-19 are found to decrease with age (Bordalo et al., 2020) yet that regions with less risk-takers and larger older population are found to increase their time staying home (Chan et al., 2020).

Finally, our paper contributes to the literature on the relationship between emotions and mood on the one hand and risk-taking (see Lerner and Keltner (2001), Fehr-Duda et al. (2011), or Otto et al. (2016), for example) and pro-social behaviour (see Dunn et al. (2008), Aknin et al. (2013), Drouvelis and Grosskopf (2016), or Falk and Graeber (2020), for example) on the other.

Study 1:

Cross-Sectional Evidence on Regional Happiness and Observed Regional Compliance

Throughout the world, in the winter and spring months of 2020, different countries (and different regions within countries) introduced lockdowns to contain the spread of Covid-19.

They were introduced in different places at different points in time, and they varied regarding their severity, depending on local and regional characteristics as well as number of confirmed cases and deaths. It is estimated that, by late March 2020, more than 100 countries had introduced either full or partial lockdowns (BBC, 2020).

Data and Methods. To study whether past regional happiness predicts observed regional compliance during lockdowns, we used cross-sectional data from the Gallup World Poll, a nationally representative survey which is conducted annually in more than 160 countries worldwide and which includes data on about 1,000 respondents' happiness alongside a wide range of individual, household, and regional characteristics in each country. We merged these data with two other datasets at the regional level: the Oxford COVID-19 Government Response Tracker (Hale et al., 2020), which includes daily data on the stringency of lockdown measures (at the country level) as well as confirmed cases and deaths (at the regional level); and the Google COVID-19 Community Mobility Reports, which include daily, regional data on smartphone recorded geographical movement to various areas, which we took as objective measures of compliance behaviour (ActiveConclusion, 2020; Google, 2020).

Our outcomes were daily percentage changes in smartphone recorded geographical visits to (or time spent in) in residential, retail or recreation, grocery or pharmacy, parks, transit, and workplace areas. These daily changes were compared to an average baseline day between January 3 and February 6, 2020. Our variable of interest was life evaluation (also known as the *Cantril ladder*, cf. Cantril, 1965). We regressed regional-level geographical mobility during Covid-19 lockdowns in 2020 on regional-level happiness in 2019, controlling for individual, household, and regional characteristics; the regional number of confirmed cases and deaths; and week, weekday, and country fixed effects. We restricted our analysis to periods where the stringency of lockdown measures was (at least) as high as that observed during the 'strict' lockdown period in the UK. We imposed this

restriction to maximise comparability between Studies 1 to 3 (our results continue to hold when lifting it). Our sample included data on between 48,520 and 50,966 adult respondents (depending on outcome) within 892 regions in 49 countries. See the Supplementary Materials on Study 1 for model specifications and summary statistics.

Results. We found that higher regional-level happiness in 2019 is associated with higher regional-level compliance, subsequently during Covid-19 lockdowns in 2020. In particular, we found that a one-point increase in life evaluation (measured on a zero-to-ten scale) in 2019 is associated with decreases between ten and 22 percent in visits to retail or recreation, grocery or pharmacy, parks, transit, and workplaces (Supplementary Materials Table S.1.1). Mobility in residential areas, on the contrary, increases by about six percent. Tables S.1.2 and S.1.3 show findings for positive and negative affect: while positive affect mirrors life evaluation, albeit with smaller effect sizes, we found the opposite for negative affect. Higher levels of negative affect in 2019 are associated with less regional-level compliance behaviour in 2020, as manifested in more time spent in grocery or pharmacy, transit, and workplaces, as well as less in residential areas.

Study 2:

Cross-Sectional Evidence on Individual Happiness

and Self-Reported Individual Compliance

We next studied whether present individual happiness predicts individual compliance during lockdowns. In contrast to before, we now looked at self-reported compliance behaviour, rather than observed geographical mobility.

Data and Methods. We used cross-sectional data from the Imperial College London-YouGov Covid-19 Behavioural Tracker, an international survey which has been running in 29 countries since April 2020 and which includes data on about 21,000 respondents' happiness alongside individual and household characteristics in each week, with a particular focus on

behaviour in response to Covid-19 and lockdown (Jones and YouGov Plc, 2020). We again merged these data with the Oxford COVID-19 Government Response Tracker to include the stringency of lockdown measures (at the country level) as well as confirmed cases and deaths (at the regional level).

Our main outcome was the extent to which a respondent reported to be willing to self-isolate for seven days if asked by a healthcare professional or public health authority. Other outcomes included the frequency of complying with 20 common preventive behaviours, for example wearing a face mask, for which we created an index of compliance. We regressed self-reported compliance behaviour on respondents' happiness during lockdowns, controlling for individual and household characteristics; the regional number of confirmed cases and deaths; and week, weekday, and country fixed effects. We restricted our analysis to respondents who (and whose cohabitants) had never been tested for Covid-19 and who had never had any symptoms. As before, we restricted our analysis to periods where the stringency of lockdown measures was (at least) as high as that observed during the 'strict' lockdown period in the UK for comparability between Studies 1 to 3 (our results continue to hold when lifting it). Our sample included data on between 12,520 and 38,910 adult respondents (depending on outcome) in 20 countries. See the Supplementary Materials on Study 2 for model specifications and summary statistics.

Results. We found that higher happiness of respondents is associated with more self-reported compliance behaviour during lockdowns. Associations are highly significant at the one percent level, but effect sizes are smaller than with observed mobility: a one point increase in life evaluation (measured on a zero-to-ten scale) increases respondents' willingness to comply with authorities' recommendations by about one percentage point. Their index of compliance behaviour increases by about one percent of a standard deviation (Supplementary Materials Table S.2.1). Table S.2.2 shows that life evaluation has consistent, significant positive associations with self-reported compliance with various preventive

behaviours, including washing hands or using sanitisers, avoiding shopping, or avoiding transit and crowded areas.

Study 3:

Longitudinal Evidence on Individual Happiness and Self-Reported Individual Compliance

We finally studied how present individual happiness predicts self-reported individual compliance longitudinally within individuals, using the example of a single country: the UK. The full UK lockdown officially started on Monday, March 23, 2020, after a prime-time television broadcast by Prime Minister Boris Johnson appealing to the general public to stay at home. This came after the Prime Minister had already ordered all pubs, cafés, restaurants, bars, and gyms to close, and after the Chancellor of the Exchequer had announced that the taxpayer would meet 80 percent of the wages of employees who could not do their work under lockdown. At this point, many people were already voluntarily staying at home. As elsewhere, the nationwide lockdown was essentially a curfew under which people should leave their homes only for several reasonable excuses, including essential shopping or one outdoor exercise per day. It effectively ended on Sunday, May 10, 2020, when the Prime Minister announced a three-step plan for going back to normality. As of the next day, certain non-essential workers in England were encouraged to go back to work and unlimited outdoor exercise was allowed (still subject to physical distancing).

Data and Methods. We used longitudinal data from the University College London Covid-19 Social Survey, a novel weekly online panel of more than 70,000 individuals in England, Wales, Scotland, and Northern Ireland, which started on March 21, 2020, and is still ongoing. We limited our analyses to the "hard" lockdown period, covering the time from March 20 to May 10, 2020. We further restricted it to respondents who identify as non-key workers (leading to the exclusion of essential workers, for example in health or social care,

who were not in lockdown); respondents who report to have never had Covid-19 themselves; and respondents who report to have never had contact with people who had contracted the virus. Our analyses were robust to lifting these restrictions.

We looked at a range of self-reported outcomes of civic compliance. These included (i) the number of days during the past seven days the respondent reports to have stayed at home and not left the house; (ii) whether the respondent reports to be either fully, partially, or not at all self-isolating at present; and (iii) the degree to which the respondent reports to comply with government recommendations. Fully self-isolating means not leaving home at all, partially self-isolating means complying with stay-at-home recommendations and leaving home only for necessary activities, and not at all self-isolating means complying with stay-at-home recommendations and living life as normally as possible. Our primary variable of interest was life satisfaction. Throughout our analyses, we controlled for a wide range of observables, including demographics, socio-economic characteristics, preference for socialisation, Covid-19 knowledge, confidence in government and the public health service, the Big-5 personality traits, mental health (PHQ-9 for depression and GAD-7 for anxiety), and the average daily new number of both Covid-19 cases and Covid-19 deaths at the level of the constituent countries of the UK (England, Wales, Scotland, and Northern Ireland), obtained from the Oxford COVID-19 Government Response Tracker.

We started with simple pooled OLS regressions which do not account for the panel dimension of the data, and then made our models successively more restrictive: first, we accounted for individual fixed effects (time-invariant unobservables and observables at the individual level) using both with-transformation and first-differences. Then, we allowed for lagged compliance (up to a second lag as compliance behaviour followed an AR(2) process) to influence current compliance behaviour, applying dynamic panel data models using Arellano-Bond estimators. In these models, past compliance is held constant to explain current compliance behaviour jointly with current happiness. We also included week-day,

area (various degrees of urbanisation), and constituent country (England, Wales, Scotland, and Northern Ireland) fixed effects. Our sample included data on between 28,897 and 34,378 adult respondents (depending on outcome and model). See the Supplementary Materials on Study 3 for model specifications and summary statistics.

Results. Table 2. shows our central result. We found that individuals who report higher levels of life satisfaction are significantly more likely to report higher levels of civic compliance.

[Table 2 about here]

This is especially true for the number of days during the past seven days the respondent reports to have stayed at home and not left the house. A one-unit increase in life satisfaction on a zero-to-ten scale increases the number of weekdays stayed at home by about 0.2 (about 1% of a standard deviation) in our most restrictive model (our Arellano-Bond dynamic panel data estimator). The size of the effect is about the same as anxiety (also about 1% of a standard deviation), but less than confidence in government or the public health service (both about 3%). Impacts on other self-reported measures of civic compliance depend somewhat on the model chosen, but broadly confirm that happier individuals are more likely to show more compliance.

Taking forward our main outcome, the number of weekdays stayed at home, we next used a categorical instead of a numerical measure of life satisfaction in our regressions. Our most restrictive model showed that the association between happiness and civic compliance is primarily driven by people with above average happiness (Supplementary Materials Table S.3.2). The size of the association is strongest for individuals who report a life satisfaction of seven or above on the zero-to-ten scale (the average life satisfaction is about six). Notably, the first-differences estimator showed that reductions in life satisfaction are associated with less

days, while increases are associated with more weekdays stayed at home (discounting the outlier for individuals changing from zero to ten life satisfaction points).

Next, we regressed the number of weekdays stayed at home on respondents' life satisfaction in the current and in the previous week, at the same time, to look at temporal dynamics. While current life satisfaction has a significant positive association with the number of weekdays stayed at home, the association with past life satisfaction turns out mostly negative and less significant (Supplementary Materials Table S.3.4). This is especially true for the Arellano-Bond dynamic panel data estimator, which also controls for the past number of weekdays stayed at home.

Finally, we ran regressions for two groups of people separately, to study underlying motivations for compliance behaviour: people who are at high risk (defined as being above 60 years of age or having certain medical preconditions, including high blood pressure, diabetes, and heart and lung disease) *versus* people who are at low risk (being below 60 years and having no relevant preconditions). We first looked at the two groups of people during the entire lockdown period (Supplementary Materials Table S.3.6) and then partitioned the lockdown period into two parts of roughly equal duration, by interacting life satisfaction with a dummy for the pre-April 15 period (Supplementary Materials Table S.3.8).

Studying the entire lockdown period first, we found that associations between happiness and compliance are stronger for the high-risk group. For the low-risk group, associations are weaker and insignificant. Looking at the partitioned lockdown period, we found a positive association between happiness and compliance for the high-risk group throughout the lockdown period, as indicated by the significant, positive main effect of life satisfaction (except for the Arellano-Bond estimator, which also failed the Hansen test). For the low-risk group, however, we found an insignificant main effect of life satisfaction and a positive significant interaction between life satisfaction and the pre-April 15 dummy. This suggests that, while happiness is positively associated with compliance for the low-risk group

in the first half of lockdown, this is not the case in the second half, with an indication for a slightly negative association (the main effect has a negative sign but fails to reach significance).

The Supplementary Materials on Study 3 include a full set of tables that replicated the previous results by additionally accounting for a linear time trend (week fixed effects), which confirmed our results. Our results also held when jointly inserting linear, quadratic, and cubic time trends; when using a balanced panel to account for out-of-sample selection; and when clustering standard errors at the daily date level. Table S.3.10 replaced life satisfaction with worthwhileness of things in life (as a eudemonic measure of subjective wellbeing), which showed similar results. Finally, we confirmed our previous findings on changes in Google smartphone recorded geographical movement to various areas using this sample (Table S.3.11).

Discussion

Throughout our studies, we found that higher levels of past and present happiness predict higher levels of civic compliance during Covid-19 lockdowns, regardless of whether we measured compliance behaviour objectively using observed changes in Google smartphone recorded geographical movement to different areas or subjectively using self-reports of survey participants. We showed that this relationship holds cross-sectionally between regions in countries as well as longitudinally when looking at within-individual variation in happiness and compliance of a large number of survey participants in the UK. For this longitudinal analysis, we used (dynamic) panel data estimators, holding constant a wide range of time-varying observables, time-invariant unobservables and observables, and lagged compliance. Accounting for unobservables matters greatly, as differences between pooled OLS and panel data estimators suggest, pointing towards the importance of longitudinal analyses. Figure 1 summarises the main findings from our regression analyses, by showing the impact of a one-

standard deviation change in happiness on all outcomes across Studies 1 to 3, measured in terms of standard deviations (tenth of a standard deviation in case of observed time spent in geographical areas).

[Figure 1 about here]

We found that the relationship between happiness and compliance holds for different measures of happiness, including evaluative (life evaluation and satisfaction), experiential (positive and negative affect), and eudemonic measures (how worthwhile things in life feel). We also found that reductions in life satisfaction as well as negative affect are associated with less compliance, in line with Leith and Baumeister (1996). Associations are modest (about a third of those between confidence in government or the public health system and compliance). This is somewhat expected, though: our models yield associations for residual happiness that is left over after netting out a wide range of observables and unobservables.

Our finding that happiness, on average, predicts civic compliance during Covid-19 lockdowns is in line with the predictions of the mood maintenance (Isen and Patrick, 1983; Johnston and Tversky, 1983; Carlson et al., 1988) as opposed to the affect infusion model (Forgas, 1995, 2010; Forgas and Tan, 2013). Underlying motivations for compliance behaviour, however, do not seem to be uniformly distributed in the population. We found associations between happiness and compliance to be stronger for high-risk individuals, who are typically older and/or who have certain medical preconditions, suggesting that, when stakes are high, risk-avoidance is likely to be the predominant motivation underlying compliance (see Table 1). This relationship is less clear for younger and healthier individuals. Our analysis of the UK lockdown seems to suggest that, for these individuals, happiness increased compliance in the first half of lockdown but did not do so in the second (or even decreased it). This seems to suggest that, while younger and healthier individuals may have

been motivated either by risk-avoidance or pro-sociality (or both) at the beginning of lockdown, their motivation may have changed as the lockdown went on. In fact, a negative association between happiness and compliance in the second half of lockdown may be suggestive of a decrease in pro-sociality (see Table 1).

As this discussion suggests, the predominant motivation underlying compliance is probably context-dependent: the same person may be motivated by risk-avoidance in one context at one point in time, and pro-socially in another context at another point in time. It is difficult to disentangle these empirically: the mood maintenance model makes the same predictions about an increase in happiness on compliance for both risk-avoidance and pro-social motivations (only a decrease, as was the case for younger and healthier individuals, points towards a change in pro-sociality). Deeper mechanisms behind pro-social motivation may be diverse, ranging from sympathy and compassion (especially towards high-risk individuals) (Eisenberg, 2000) to reciprocity or self-image. Our data are not granular enough to disentangle these. Likewise, they are not granular enough to disentangle deeper mechanisms behind risk-avoidance: for example, risk-avoidance may be directed towards oneself (self-regarding) or towards family and friends (other-regarding), which is more pro-social in nature. That said, risk-avoidance *versus* pro-social motivations may be an artificial dichotomisation, although a useful one for analytically reasons. It is likely that legal risk (from not complying with recommendations) is more uniformly distributed across the age and health gradient.

An alternative motivation underlying compliance may be the emergence of social norms, whereby risk-avoidance or pro-sociality may become a social norm. People may then be primarily motivated by adhering to a social norm rather than the specific content of that norm. A positive association between happiness and compliance may then result from adherence to a social norm, and vice versa (Carlson et al., 1983; Hertel et al., 2000; Tan and Forgas, 2010). Although our data do not allow us to rule out this possibility, we note that

social norms typically take some time to arise and the seven weeks of UK lockdown were (arguably) rather short.

Conclusion

Around the world, governments introduce either partial or full lockdowns to contain the spread of Covid-19, asking their citizens to adhere to unprecedented measures restricting their personal freedoms. As the legal enforcement of wide-ranging lockdowns through policing is practically impossible, governments must rely on citizens' compliance. Studying the determinants of compliance behaviour is, therefore, key to designing policies to contain the pandemic.

In this paper, we found that people's happiness, regardless of whether it is measured as life evaluation or satisfaction, positive or negative affect, or how worthwhile things in life feel, is predictive of their compliance. We gave suggestive evidence that high-risk individuals, who are typically older and less healthy, are predominantly motivated by risk-avoidance, whereas motivations of younger and healthier individuals are less clear and probably dependent on context. Sheth and Wright (2020), using a sample of university students, found that neither risk nor social preferences or pre-existing health conditions are predictive of compliance. The motivations of younger and healthier people, therefore, remains an important area for future research. We found that negative affect is associated with less compliance, a finding that is interesting against the background of reactance bias, rebelliousness, and surging protests against lockdown measures observed in many countries.

There are several limitations to this paper. Although we employed three large-scale, cross-sectional and longitudinal surveys covering several countries, each of them is likely to underrepresent the most reluctant non-compliers (they are unlikely to participate in surveys in the first place). Besides this issue of external validity, we were unable to formally claim causality. Finally, our data are not detailed enough to identify the specific mechanisms by

which happiness raises compliance. This is an important area for future research, especially for younger and healthier individuals. That said, future data collection efforts should include measures of happiness and compliance alongside specific measures for mechanisms.

Our findings matter at a practical level: for individuals, they highlight the importance of being aware of the role that one's own mood plays for one's behaviour. For policy, there are both direct and indirect implications: policy-makers could directly device interventions aimed at raising mental wellbeing during lockdowns, targeting, in particular, population groups at risk of low mental wellbeing. Indirectly, policy-makers could target policies and policy communication more precisely to match underlying motivations for compliance, be they risk-avoidance or pro-social. More generally, our findings show that there is a positive correlation between happiness and compliance behaviour, so a stronger focus on wellbeing in policy-making could help increase compliance with some of the toughest measures and challenges of our time.

Figure 1: Summary of Main Findings

Notes: See Supplementary Materials Table S.1.1 for corresponding table to main findings of Study 1, Supplementary Materials Table S.2.1 for Study 2, and Table 3.1 Column 4 in the main text for Study 3. See Supplementary Materials for detailed model descriptions. Shown coefficients for Study 3 come from Arellano-Bond (dynamic panel data) estimator. All coefficients are covariate-adjusted. All variables were standardised with mean zero and standard deviation one. Confidence bands are 95%.

Table 1: Theoretical Predictions About the Effect of Happiness on Civic Compliance

<i>Civic Compliance Behaviour</i>	<i>Affect Infusion Model</i>	<i>Mood Maintenance Model</i>
Risk-Avoidance Motivation	Happiness decreases compliance Mechanism: change in shape of probability-weighting function (less weight attached to risky prospects) (Forgas, 1995; Forgas and Tan, 2013)	Happiness increases compliance Mechanism: loss aversion (people want to retain positive affect) (Isen and Patrick, 1983; Johnston and Tversky, 1983)
Pro-Social Motivation	Happiness decreases compliance Mechanism: change in internally <i>versus</i> externally oriented mental processing (more internally oriented mental processing promotes selfishness) (Tan and Forgas, 2010)	Happiness increases/decreases compliance Mechanism: increase in compliance if promotion of self-image, favourable appearance in social comparisons, good feelings more generally; decrease in compliance if compliance becomes too unpleasant (Carlson et al., 1988)

Supplementary Materials

Study 1: Cross-Sectional Evidence on Regional Happiness and Observed Regional Compliance

We estimated the following regression model:

$$compliance_{rt} = a + \beta_1 happiness_{r2019} + X_{rt}\beta_2' + \eta_{wd} + \eta_w + \mu_c + \varepsilon_{rt} \quad (E.1.1)$$

where $compliance_{rt}$ was compliance behaviour in region r on date d , $happiness_{r2019}$ was the predicted happiness in region r in year 2019, X was a vector of controls, η_{wd} were weekday fixed effects, η_w were calendar week fixed effects, and μ_c were country fixed effects. The controls included indices of local economic confidence, unemployment, law and order, and social life, as well as the log numbers of both daily confirmed Covid-19 cases and daily confirmed Covid-19 deaths. Predicted happiness was obtained from an auxiliary model that regressed a respondent's happiness on age, gender, marital status, education, employment status, log household income, the number of adults and children in the household, and the degree of urbanisation.

Compliance behaviour was the percentage change in smartphone recorded geographical mobility in various areas, originating from Google COVID-19 Community Mobility Reports (ActiveConclusion, 2020; Google, 2020). Happiness was either life evaluation or indices of positive or negative affect, originating from the Gallup World Poll. Life evaluation was obtained from a single-item eleven-point Likert scale which asked respondents to imagine themselves on a ladder with steps numbered from zero at the bottom to ten at the top, whereby zero represents the worst possible and ten the best possible life (the so-called *Cantril ladder*, cf. Cantril, 1965). The indices of positive or negative affect, which are bounded between zero and 100, were constructed by averaging across a set

of yes-no questions that asked respondents about their emotional experiences during the previous day. For positive affect, these include whether respondents experienced feelings of happiness and enjoyment, and whether they smiled and laughed a lot. For negative affect, these include whether respondents experienced feelings of sadness, worry, and anger. The stringency of lockdown measures and the log numbers of both daily confirmed Covid-19 cases and daily confirmed Covid-19 deaths were obtained from the Oxford COVID-19 Government Response Tracker.

We restricted our sample to observations where the stringency of lockdown measures was equal to or greater than 72.48 to ensure comparability between Studies 1 to 3. A stringency of 72.48 corresponds to the stringency observed during the "hard" UK lockdown period.

The model was estimated using ordinary least squares. Robust standard errors were clustered at the regional level (alternatively, robust standard errors clustered at the date level yielded the same results).

Study 2: Cross-Sectional Evidence on Individual Happiness and Self-Reported Individual Compliance

We estimated the following model:

$$compliance_i = a + \beta_1 happiness_i + X_i \beta_1' + \eta_{wd} + \eta_w + \mu_c + \varepsilon_i \quad (E.2)$$

where $compliance_i$ was the compliance behaviour of individual i , $happiness_i$ was the happiness of individual i , X was a vector of controls, η_{wd} were weekday fixed effects, η_w were calendar week fixed effects, and μ_c were country fixed effects. The controls included age, gender, employment status, and the number of adults and children in the household at the individual as well as the log numbers of both daily confirmed Covid-19 cases and daily confirmed Covid-19 deaths at the country level.

Compliance behaviour was the degree to which a respondent reported to be willing to self-isolate for seven days if asked by a healthcare professional or public health authority. It was obtained from a single-item five-point Likert scale ranging from one ("very willing") to five ("very unwilling"). We dichotomised this item such that it equals one if a respondent was "very willing" or "somewhat willing" to comply, and zero else. Moreover, compliance behaviour was captured by the frequency with which a respondent reported to be complying with 20 common preventive behaviours. These were obtained from single-item five-point Likert scales ranging from one ("always") to five ("not at all"). We again dichotomised this item such that it equals one if a respondent was "always" or "frequently" complying, and zero else. We created an index of compliance, by standardising each item and then calculating a weighted sum, whereby we used the inverse of the variance-covariance matrix of the standardised items as weights. This ensured that highly correlated items (which contain little new information) received less weight. Happiness was life evaluation. It was obtained from a single-item eleven-point Likert scale which asked respondents to imagine themselves

on a ladder with steps numbered from zero at the bottom to ten at the top, whereby zero represents the worst possible and ten the best possible life (the so-called *Cantril ladder*, cf. Cantril, 1965). All data originated from the Imperial College London-YouGov Covid-19 Behavioral Tracker, except for the stringency of lockdown measures and the log numbers of both daily confirmed Covid-19 cases and daily confirmed Covid-19 deaths, which were obtained from the Oxford COVID-19 Government Response Tracker.

We restricted our sample to observations where the stringency of lockdown measures was equal to or greater than 72.48 to ensure comparability between Studies 1 to 3. A stringency of 72.48 corresponds to the stringency observed during the "hard" UK lockdown period. We also restricted our sample to individuals who (and whose household cohabitants) reported to have never been tested for Covid-19 and who reported to have never had any symptoms.

The model was estimated using ordinary least squares. Robust standard errors were clustered at the date level.

Table S.2.1: Life Evaluation and Self-Reported Civic Compliance (Imperial College London-YouGov Covid-19 Behaviour Tracker, 20 Countries, Year 2020)

	Complying With Recommendations (1)	Complying With Preventive Behaviours (2)

Study 3: Longitudinal Evidence on Individual Happiness and Self-Reported Individual Compliance

We estimated the following regression models:

$$compliance_{it} = a + \beta_1 happiness_{it} + X_{it}\beta_2' + \eta_{wd} + \mu_c + \varepsilon_{it} \quad (E.3.1)$$

$$compliance_{it} = a + \beta_1 happiness_{it} + X_{it}\beta_2' + \eta_{wd} + \mu_c + \mu_i + \varepsilon_{it} \quad (E.3.2)$$

$$compliance_{it} = a + \beta_1 happiness_{it} + X_{it}\beta_2' + \beta_3 compliance_{it-1} + \eta_{wd} + \mu_c + \mu_i + \varepsilon_{it} \quad (E.3.3)$$

where $compliance_{it}$ was the compliance behaviour of individual i in week t , $happiness_{it}$ was the happiness of individual i in week t , X_{it} was a vector of controls, η_{wd} were weekday fixed effects, μ_c were country fixed effects, and μ_i were individual fixed effects. The controls included age, gender, marital status, ethnicity, education, employment status, income, dwelling type, the number of rooms in the dwelling, the number of children and adults in the household, the residential area (city, large town, small town, village, hamlet, or isolated dwelling), the number of close friends, the frequency of socialising (in normal times), self-assessed knowledge about Covid-19, confidence in government, confidence in the public health system, the Big-5 personality traits, measures of depression (PHQ-9) and anxiety (GAD-7), as well as the log numbers of both daily confirmed Covid-19 cases and daily confirmed Covid-19 deaths at the country level.

Compliance behaviour was measured as (i) the number of days during the past seven days the respondent reported to have stayed at home and not left the house (zero-to-seven scale); (ii) whether the respondent reported to be either fully, partially, or not at all self-isolating at present (binary indicators); and (iii) the

degree to which the respondent reported to comply with government recommendations (one-to-seven Likert scale). Fully self-isolating means not leaving home at all, partially self-isolating means complying with stay-at-home recommendations and leaving home only for necessary activities, and not at all self-isolating means complying with stay-at-home recommendations and living life as normally as possible. Happiness was measured as life satisfaction, which was obtained from a single-item eleven-point Likert scale asking respondents: "Overall, in the past week, how satisfied have you been with your life?" Answers ranged from zero ("not at all") to ten ("completely"). As an alternative measure, we also looked at how worthwhile things in life feel, which was obtained from a single-item eleven-point Likert scale asking respondents: "In the past week, to what extent have you felt the things you are doing in your life are worthwhile?" Answers ranged from zero ("not at all") to ten ("completely"). We adjusted both variables to account for their retrospective nature. The stringency of lockdown measures and the log numbers of both daily confirmed Covid-19 cases and daily confirmed Covid-19 deaths were obtained from the Oxford COVID-19 Government Response Tracker.

We restricted our sample to the "hard" UK lockdown period, which was from March 23 to May 10, 2020. We also restricted our sample to respondents who identified as non-essential workers (excluding, for example, people working in hospitals), who reported to have never had Covid-19 themselves and who reported to have never had any contact with people who had contracted the virus.

Equation E.3.1 was estimated using pooled ordinary least squares, Equation E.3.2 using ordinary least squares respectively after within-transforming and first-differencing, and Equation E.3.3 using the Arellano-Bond estimator (generalised-method-of-moments). Robust standard errors were clustered at the individual level (alternatively, robust standard errors clustered at the date level yielded the same results).
