Abstract

Memory-guided predictions can improve event comprehension by guiding attention and the eyes to the location where an actor is about to perform an action. But when events change, viewers may experience predictive looking errors and need to update their memories. In two experiments ($Ns = 38$ and 111), we examined the consequences of mnemonic predictive looking errors for comprehending and remembering event changes. University students watched movies of everyday activities with actions that repeated exactly and actions that repeated with changed features—for example, an actor reached for a paper towel on one occasion and a dish towel on the next. Memory guidance led to predictive looking errors that were associated with *better* memory for subsequently changed event features. These results indicate that retrieving recent event features can guide predictions during unfolding events, and that error signals derived from mismatches between mnemonic predictions and actual events contribute to new learning.

Keywords: action observation, event cognition, memory updating, mnemonic prediction error, predictive looking

Statement of Relevance

The present research employs a rigorous behavioral and physiological approach to identify the mechanisms involved in updating memories for naturalistic actions. This research is of general interest because it combines theory and methods across areas of cognitive science and cognitive neuroscience in a highly naturalistic paradigm. Our theoretically motivated approach leverages methodological innovations from the action observation, memory updating, event cognition, and visual attention literatures. An attractive feature of the paradigm is that it goes beyond single trial action observation by depicting an actor performing sequences of actions across physical locations (e.g., various rooms in her house). The results implicate a critical role for mnemonic predictions in updating memory for changed event features. These findings will improve our understanding of how people remember related content from separate occasions and the role that expectations based on earlier observations play in how well new information is learned.

Understanding Everyday Events:

Predictive Looking Errors Drive Memory Updating

Predicting the actions of others is essential for skilled social interactions. For example, to cooperate in preparing dinner, one may need to anticipate when their partner will use the sink to wash vegetables. Prediction can improve action comprehension and facilitate one's own action planning (Gredebäck, 2018; Gredebäck & Falck-Ytter, 2015). Anticipating the future based on the past is adaptive because people often repeat behaviors. But when situations change, people behave differently. If the partner in the example above purchased pre-washed vegetables on a later occasion, she may bypass washing them in the sink, leading the observer to experience a mnemonic prediction error. Viewers' comprehension of such unexpected action changes may require registering such mismatches between predicted and actual events.

Action observation studies show that adult viewers make online predictions about future actions, especially actions they have experienced. Viewers look ahead to contacted objects (Eisenberg et al., 2018; Flanagan & Johansson, 2003; Hayhoe et al., 2003; Land & McLeod, 2000) and learn to predict object trajectories from repeated sequences (Barnes et al., 2005; Diaz et al., 2013). Infants learn to predict manual actions that are repeatedly performed (Cannon et al., 2012; Falck-Ytter et al., 2006), show positive correlations between predictive looking and their experience performing the actions (Cannon et al., 2012; Gredebäck et al., 2018; Melzer et al., 2012), and look earlier when observing recently learned actions (Gerson & Woodward, 2014). Thus, memory for past actions can guide action prediction and comprehension.

When actions change across occasions, mnemonic predictions trigger surprise responses that may stimulate new learning and update predictions for future actions (Gredebäck et al., 2018). Infant eye tracking studies show longer looking times to events that violate expectations

about world knowledge (Gredebäck et al., 2018; Juvrud et al., 2019; Stahl & Feigenson, 2015). Infants and children also show greater pupil dilation when actions end unexpectedly (Gredebäck et al., 2018; Juvrud et al., 2019). Such prediction errors increase exploration and new learning. For example, infants who watched a ball unexpectedly roll through a wall later explored the ball more than infants who had seen a ball stop. When infants were taught that the ball squeaked, infants whose expectations has been violated better remembered the new property of the ball (Stahl & Feigenson, 2015). These findings show that when an action violated world knowledge, infants actively updated their understanding of the object's properties.

Conditions associated with prediction errors are also associated with memory updating. When learned image sequences later include unexpected images that trigger prediction errors, memory is reduced for expected but no longer relevant images (Kim et al., 2014). In addition, after people learn to associate consistently valenced words with a scene category, pairing similar scenes with oppositely valenced words leads to better memory (Greve et al., 2017). Similarly, switching sequential contingencies such that symbol cues are first followed by objects from one semantic category and then another enhances recollection for unexpected objects (Kafkas & Montaldi, 2018). Also, prediction errors based on memory for virtual scenes enhance subsequent memory, with the benefit increasing with the number of changed features (Bein et al., 2020). When viewing action sequences, interrupting repetitions before expected outcomes distorts memory for prior events, indicating a form of error-driven memory updating (Sinclair & Barense, 2018). Relatedly, during basketball viewing, prediction errors and subsequent memory are associated with increased pupil size and cortical activity shifts (Antony et al., 2020).

When viewers see an actor perform everyday activities that change over time, prediction errors may stimulate better encoding. In one series of experiments, viewers watched an actor

perform action sequences on two occasions with some actions changing (Wahlheim & Zacks, 2019). For example, while the actor initially retrieved a *bath towel* from the closet, she later opened the closet the same way but retrieved a *hand towel*. Memory for changed actions was better when changes were noticed and later recollected. Also, greater neural reinstatement of the original actions before viewing changed actions was associated with better subsequent memory (Stawarczyk et al., 2020). This suggests that anticipating repeated actions triggered updating for changes. Although neural reinstatement may be necessary for mnemonic predictions (Bein et al., 2020), this measure alone does definitively index predictive processing.

In the current study, we assayed mnemonic prediction error in this *everyday changes* paradigm using anticipatory eye movements as a converging measure. In the first session, participants watched two movies of an actor performing everyday activity sequences depicting two fictional “days” in her life (Day 1 and Day 2 movies). *Changed activities* started with the same actions in both movies but ended with different actions in each movie, whereas *repeated activities* started and ended with the same action in both movies. Experiment 2 also included *control activities* with actions that were only performed in the second movie. Eye movements were recorded while participants watched the movies. In the second session, one week later, participants recalled Day 2 activity features (i.e., contacted objects), indicated whether the contacted objects had changed between movies, and if so, recalled the Day 1 features.

Changed Day 2 features are better remembered when participants can also remember that those features had changed and the original Day 1 features (Garlitch & Wahlheim, 2021; Hermann et al., 2021; Stawarczyk et al., 2020; Wahlheim & Zacks, 2019). According to *Event Memory Retrieval and Comparison Theory* (EMRC; Wahlheim & Zacks, 2019), the memory benefit for changed Day 2 features associated with recall of Day 1 features occurs partly because

mnemonic prediction errors stimulate encoding of new features. EMRC proposes a causal cascade in which viewers may (a) retrieve the activity's previous ending, (b) use the remembered action to predict the Day 2 ending, (c) experience a mnemonic prediction error when they view an unexpected action change, and (d) update their memory in response to that error. This view is consistent with findings of error-driven associative learning (Rescorla & Wagner, 1972).

The present two experiments tested the hypothesis that while viewing the beginnings of changed activities, predictive looking based on memory for Day 1 endings should be associated with better subsequent memory for changes, recall of Day 1 features, and memory for the changed Day 2 features. We tested this against the hypothesis that predictive processing is not necessary for changed features to be better remembered when they are recollected as such. This could occur when viewers retrieve Day 1 activities *after* viewing changed Day 2 activity endings because postdictive processes (cf. Neely et al., 1989) may be used to compare activities and improve the encoding changed activity endings.

Method

Participants

In Experiment 1, we set the sample size based on previous studies using the everyday changes paradigm to measure memory effects (Wahlheim & Zacks, 2019; $N = 36$) because no relevant previous data were available to support a power analysis. We recruited 43 participants and excluded five either because we could not track their eyes (four) or due to attrition (one). The final sample included 38 participants (13 women) ages 18-27 ($M = 20.37$, $SD = 2.17$). In Experiment 2, we ran bootstrapping power analyses using custom codes in R software (R Core Team, 2020) for each of the primary hypotheses using the data from Experiment 1. We sampled Experiment 1 data with replacement to obtain varying numbers of simulated participants. We

then ran mixed-effects models for the results of interest and determined if they were significant. We ran 1000 iterations for the recall models and 500 iterations for the eye tracking models. We determined the proportion of significant results, which provided the estimates for power. The results indicated that a sample of 90 participants would be enough to achieve 80% power. Consequently, we recruited 111 participants, anticipating that some would have to be excluded. We excluded 13 participants either because we could not track their eyes (12) or the equipment failed (1). The final sample included 98 participants (56 women) ages 18-25 ($M = 19.61$, $SD = 1.39$). All participants received course credit or \$10 per hour.

Materials and Design

Both experiments included the same two movies showing a woman actor performing sequences of everyday activities in or around her home and workplace on two fictional “days” in her life. There were two versions (A and B) of each activity that included the same peripheral features and a changed central feature that always showed her manipulating an object (e.g., inserting a key into a door lock). Figure 1A shows key moments from two versions of an example activity where the actor unlocked her front door to enter her home. In Version A, she unlocked the *doorknob*, whereas in Version B, she unlocked the *deadbolt*. The different central features in each version are displayed at the point of contact (“Contact”).

Fig. 1.*Example Activities and Interest Areas***A. Two Versions of an Example Activity** **B. Repeated Activity** **C. Changed Activity**

Note. A) Key moments from an example activity in which the actor unlocked a door. The interest period for eye tracking analysis began as she approached the door and ended when she first contacted either the *doorknob* (Version A) or *deadbolt* (Version B). The first images (Start) show the start of the interest period; the second images (Divergence) show the moment before the activity versions diverge; the third images (Contact) show the two possible contacted objects. B) Example interest areas for a repeated activity. C) Example interest areas for a changed activity. B and C) Yellow boxes are interest areas for target (blue) and alternate (red) objects. The designation of target and alternate objects was the same in both movies for repeated activities and switched from the Day 1 to Day 2 movie for changed activities. The images are shown in black-and-white here to enhance the visual contrast of the yellow boxes showing the interest areas. The complete movies were shown in color and were not altered to indicate interest areas. The movies can be downloaded from the OSF: <https://osf.io/w8skp/>.

Experiment 1 used a 2 (Activity Type: repeated vs. changed) within-subjects design to manipulate the relationship between activities in each movie. Each movie included 44 critical activities (22 per condition) and 20 filler activities (10 per condition) that served to maintain narrative continuity (64 activities total). We counterbalanced the assignment of activity versions across activity types and movies in the following way. First, we created a Day 1 movie that included all critical activities assigned to either Version A or B. No more than three activities of the same version appeared sequentially. Then, we created another Day 1 movie, switching all the activity versions (i.e., Version A activities became Version B activities and vice versa). Finally, we created two Day 2 movies—one that included all Version A activities and one that included all Version B activities. The combinations of the Day 1 and Day 2 movies produced four experimental formats.

Experiment 2 included the same repeated and control conditions as in Experiment 1, but also included a Control condition with activities that only appeared in the Day 2 movie. Thus, it used a 3 (Activity Type: repeated vs. control vs. changed) within-subjects design. We assigned twice the number of activities to the changed condition than the other conditions to focus power on changed activities, which were of primary theoretical interest. The Day 1 movies included 33 critical activities (22 changed and 11 repeated) and 20 filler activities (10 changed and 10 repeated) for a total of 53 activities. The Day 2 movies included 44 critical activities (22 changed, 11 repeated, and 11 control) and 20 filler activities (10 changed and 10 repeated) for a total of 64 activities. The activities were counterbalanced in the same way as Experiment 1.

Both experiments used the same cued recall test items. The test included 64 questions probing memory for all activities from the Day 2 movie. Cues asked about the central features

that could have changed. For example, the cue for the door-unlocking example in Figure 1 asked about the central *lock* feature (i.e., “Which lock did the actor unlock to enter her home?”).

Procedure

Figure 2 displays a schematic of the two experimental sessions, which were separated by approximately one week (Experiment 1: $M = 7.07$ days, $SD = 0.81$ days, $range = 7-11$ days; Experiment 2: $M = 7.07$, $SD = 0.50$, $range = 6-10$ days). Both experiments used the same procedure with one exception noted below. The exact instructions shown to participants are available in the Supplemental Material. Movies were shown on a 19 in (74 cm) monitor (1440 × 900 resolution) at a 1280 × 720 aspect ratio using SR Research Experiment Builder software (SR Research Ltd., Mississauga, ON, Canada). Gaze location was recorded from the right eye using an infrared pupil-corneal eye tracker (EyeLink 1000; SR Research Ltd., Mississauga, ON, Canada) that sampled at 1000 Hz. Participants placed their head against a chin/forehead rest to minimize head motion. The camera was positioned 52 cm from the top of the rest. The viewing distance was 58 cm from the rest with a viewing angle of 38.6°.

Fig. 2.*General Schematic of Events in Each Experimental Session***A. Session 1 (Day 1 and Day 2 Movies)**

Approximately one week elapsed between experimental sessions.

B. Session 2 (Cued Recall Test)

Note. A) Participants watched two movies successively during the first session. They were instructed to pay attention to the actor's activities in both movies. After a delay, participants completed (B) a second session that included a cued recall test of features from both movies. For each activity, participants first tried to recall the Day 2 feature. Then they were asked to classify if the activity had earlier changed between movies. When participants indicated that an activity had changed, they tried to recall the Day 1 feature then moved on to the next trial (blue arrows). When participants indicated that an activity had not changed, the program advanced to the next test trial (red arrow). The test instructions differed slightly between experiments (see Supplementary Material).

During Session 1, participants were told that they would watch movies of an actor performing everyday activities and to pay attention to those activities. Participants watched two different movies from ostensibly separate “days” in the actor’s life. As described above, half of the Day 2 activities included changed endings. While watching each movie, participants took short breaks between scenes showing morning, work, afternoon, and evening activities.

During Session 2, participants completed the cued recall test presented via E-Prime 2 software (Psychology Software Tools, Pittsburg, PA) in another room. They were told that they would recall activity features and indicate which features had changed between movies. Before the test, participants viewed two example clips of a hair styling activity with a changed feature. The actor styled her hair first with a comb and then with a brush. Test items then appeared individually (for a schematic of the test trial structure, see Figure 2B). On each trial, participants first recalled the Day 2 feature by typing their response. Then they indicated if the feature had changed by responding “yes” or “no” with the “1” or “2” key (Experiment 1) or by classifying the activity as repeated, changed, or only shown on Day 2, with the “1”, “2”, or “3” key (Experiment 2). When participants indicated that an activity had changed (“yes” or “changed”), they attempted to recall the Day 1 feature by typing their response. When participants indicated that an activity had not changed, the program advanced to the next trial.

Statistical Analysis

All analyses were conducted using R software. We fitted linear and logistic mixed effects models including experimental variables as fixed effects and subjects and activities (items) as random effects using functions from the *lme4* package (Bates et al., 2015). We tested for significant effects of predictor variables using the Wald test in the *Anova* function from the *car* package (Fox & Weisberg, 2019). We conducted pairwise comparisons using the *emmeans*

function from the *emmeans* package (Lenth, 2020) with the Tukey method controlling for multiple comparisons. All statistical tests were two-sided. The level for significance was set at $\alpha = .05$. The probabilities and confidence intervals below were estimated from these models.

Results

Each activity included a pair of critical objects that the actor might manipulate, such as the doorknob and deadbolt in Figure 1A. For repeated activities, the actor manipulated the same *target* object on both days—for example, she could unlock the deadbolt on both days (Figure 1B). In that case the *alternate* object on both days would be the doorknob. For changed activities, the target object in the Day 1 movie became the alternate object in the Day 2 movie, and vice versa (Figure 1C). Both repeated and changed activities appeared in both experiments. Control activities that the actor only performed in the Day 2 movie also appeared in Experiment 2. The primary eye tracking measure of interest was the proportion of time looking to the target and alternate objects while watching each activity. We report results from analyses comparing these proportions across activity types and movies from both experiments together. We also conducted exploratory analyses of pupil areas that we report in the Supplemental Material.

Proportions of Looks to Interest Areas

To characterize looking patterns as activities unfolded, the co-first authors first divided each activity into two intervals of interest (Figure 1A). The raters watched each version of each activity together and jointly decided about interval placement. The *pre-divergence* interval started when the target and alternate object were both visible and ended the moment before the actor started to move more towards the target than alternate object (e.g., the first moment her reach trajectory indicated that she was more likely to contact the deadbolt than doorknob). The *post-divergence* interval started the moment after this divergence point and ended when the actor

contacted the target object. Total interest intervals ranged from 470 to 29,200 ms ($M = 6434$ ms, $SD = 5032$ ms). Pre-divergence intervals ($range = 100$ to $16,920$ ms, $M = 5212$ ms, $SD = 3597$ ms) were significantly longer than post-divergence intervals ($range = 140$ - $13,250$ ms, $M = 1222$ ms, $SD = 2447$ ms), $t(87) = 10.61$, $p < .001$.

Because the pre- and post- divergence intervals varied in length, we divided each interval into 10 isochronous bins for analysis (20 total bins). This allowed us to compare the time course of looking behavior in terms of the relative time elapsed from the onset of each activity to the divergence point and from the divergence point to object contact, controlling for differences in duration. To analyze looking patterns as activities unfolded, we included time bin (Bin) as a categorical predictor variable in the mixed-effects models. When testing hypotheses about the effects of prior viewing on predictive looking before and after divergence points, we used separate models that only included either the first 10 bins (pre-divergence) or second 10 bins (post-divergence). For each activity, we defined spatial regions of interest by drawing polygons around the target and alternate objects (Figures 1B & C). We then recorded, for each participant, whether they looked in one or both interest areas during each time bin. In the following analyses, we report looking proportions in each interest area aggregated across all activities. In addition to the analyses reported here, we examined the consistency of looking proportion differences across activities based on pre- and post-divergence interval lengths (see Supplementary Material).

When Viewing Activities Again, Viewers Look Predictively to Previous Targets of Action

Repeated Activities. For repeated activities, the actor manipulated the same object on both days, so mnemonic predictions based on Day 1 actions should lead to more looking to Day 2 target objects. This was what we found (Figure 3, top left quadrants in both panels). In both experiments, logistic mixed-effects models were used to estimate proportions of looking to each

object of interest (Object) during both movies (Day) at each time bin (Bin). Models including Object, Day, and Bin as fixed effects (Table 1, top rows) indicated significant Object $\times$ Day interactions. Participants looked significantly more to target objects when watching the Day 2 than Day 1 movie, smallest z ratio = 9.39, $p < .001$. In contrast, they looked significantly less to alternate objects when watching the Day 2 than Day 1 movie, smallest z ratio = 2.03, $p = .043$.

Fig. 3.

Looks to Target and Alternate Objects During Movie Viewing

Note. Model-estimated proportions of looking in interest areas including target and alternate objects during interest periods for critical activities. “Start” indicates the moment the interest period began. “Divergence” indicates the point of divergence when the two activity versions first became distinguishable. “Contact” indicates the moment the actor contacted the target or alternate object. Orange dashed lines indicate looking proportions during Day 1 movie viewing. Black solid lines indicate looking proportions during Day 2 movie viewing.

The models in both experiments also indicated significant Object $\times$ Bin interactions showing the following patterns: In the pre-divergence intervals (time bins -9 to 0; from “Start” to “Divergence”), looking proportions were mostly consistent across adjacent bins. Pairwise comparisons only indicated significant increases for target objects in both experiments from bin -1 to 0, smallest z ratio = 4.83, $p < .001$. In the post-divergence intervals (time bins 1 to 10; from the bin after “Divergence” to “Contact”), looking patterns differed for target and alternate objects.

For target objects, looking proportions increased consistently until Bin 6 (Experiment 1) and Bin 7 (Experiment 2) and then began to asymptote. In contrast, for alternate objects in both experiments, there were overall decreases in looking proportions across the interest periods. Looking proportions were significantly greater in the first bin (1) than the last bin (10), smallest z ratio = 7.41, $p < .001$. However, the decrease in looking was sharpest across the three bins after the divergence point, as there were few significant differences beyond Bin 3.

There was also an Object $\times$ Day $\times$ Bin interaction in Experiment 2. To characterize this interaction, separate models with the same variables were fitted to data including only the time bins from pre- or post-divergence intervals. In the pre-divergence model (Table 2, top rows), an Object $\times$ Day interaction showed significantly greater proportions of looking to target objects in the Day 2 than Day 1 movie, z ratio = 4.76, $p < .001$, but no significant difference in the proportions of looking to alternate objects in each movie, z ratio = 1.19, $p = .234$. In the post-divergence interval, an Object $\times$ Day interaction indicated significantly greater proportions of looking to target objects in the Day 2 than Day 1 movie, z ratio = 8.55, $p < .001$, and to alternate objects in the Day 1 than Day 2 movie, z ratio = 4.33, $p < .001$. These results show that viewing experience increased predictive looking to objects the actor would contact early in each activity.

Changed Activities. For changed activities, the actor manipulated one object in the Day 1 movie but then a different object in the Day 2 movie. The objects that were manipulated on Day 1 but not Day 2 are referred to as alternate objects for Day 2 (see Figure 1C). During the early part of a changed activity on Day 2, mnemonic predictions based on actions from Day 1 movies should increase looking to the alternate object, because that object was previously the action target. After the divergence point, as visual cues provide information that the activity will

end differently, looking to the target should increase. Figure 3 (right quadrants in both panels) shows that this qualitative pattern was observed in both experiments.

For Experiment 1, a model with the same variables as in the looking proportion model for repeated activities (Table 1, bottom rows) indicated a significant Object $\times$ Day $\times$ Bin interaction. This interaction was characterized using separate models for the pre- and post-divergence intervals. In the pre-divergence interval (Table 2, bottom rows), a significant Object $\times$ Day interaction showed greater proportions of looking to both objects when viewers watched the Day 2 than Day 1 movie, with this difference being greater for alternate, z ratio = 6.01, $p < .001$, than target, z ratio = 1.99, $p = .047$, objects. These results suggest that memory for actions in Day 1 movies guided viewers' looking towards areas including objects that could be contacted in Day 2 movies, especially for areas including the earlier-contacted objects. In the post-divergence interval, a significant Object $\times$ Day interaction indicated greater proportions of looking to target objects in the Day 2 than Day 1 movie, z ratio = 10.00, $p < .001$, and to alternate objects in the Day 1 than Day 2 movie, z ratio = 2.37, $p = .018$. These results suggest that observed movement trajectories that contradicted mnemonic predictions stimulated more looking to objects that had not been contacted in the Day 1 movie.

In both experiments, there were also significant Object $\times$ Bin interactions indicating the following patterns: In the pre-divergence intervals, looking proportions were mostly consistent across adjacent bins with some exceptions. For target objects in both experiments, there were significant increases from bin -1 to 0, smallest z ratio = 5.19, $p < .001$. For target objects in Experiment 2, the first bin (-9) was significantly lower than most other bins, smallest z ratio = 3.17, $p = .049$. For alternate objects in Experiment 2, there were significant increases in bins -8, -7, -1, and 0, smallest z ratio = 3.20, $p = .045$. In the post-divergence intervals, there were

substantial differences in proportions of looking to target and alternate objects. For targets in both experiments, there were generally consistent increases in looking across adjacent bins, until Bin 7. In contrast, for alternate objects in both experiments, looking proportions decreased as activities unfolded. Looking proportions were significantly greater in the first bin (1) than last bin (10), smallest z ratio = 8.65, $p < .001$. However, the decrease in looking to alternate objects was sharpest in the four bins after the divergence point, as there were few significant differences beyond Bin 4.

Finally, in Experiment 2, there was a significant effect of Day, replicating the finding from Experiment 1 that proportions of looking to both objects were greater during Day 2 than Day 1 movies. However, in contrast to Experiment 1, neither the Object $\times$ Day nor the Object $\times$ Day $\times$ Bin interaction was significant. In sum, when watching an activity for the second time, viewers looked predictively to the target object that the actor had previously manipulated. Viewers did this starting early in the activity, before the two potential endings diverged. For changed activities, this resulted in mnemonic predictive looking errors that were subsequently corrected as the actor's hand approached the changed target object.

Cued Recall Performance

When participants were asked about features of Day 2 activities on the cued recall test, most responses were correct reports of the object manipulation seen on Day 2 (Day 2 recalls: 57% [Experiment 1], 50% [Experiment 2]) or incorrect reports of the alternate object manipulation (alternate intrusions: 20% [Experiment 1], 21% [Experiment 2]). In the example changed activity shown in Figure 1C, reporting “she unlocked the deadbolt” would be a correct Day 2 recall, and reporting that “she unlocked the doorknob” would be an alternate intrusion. Note that alternate intrusions are intrusions from episodic memory only for changed activities;

for repeated and control activities, such responses reflect false remembering of an action that was not performed but fit within the semantic context of the activity. The remaining responses included ambiguous responses (4% [Experiment 1], 9% [Experiment 2]) that were correct but did not identify a target or alternate features (e.g., “she unlocked the house”), and other errors such as recalling other activity features or omissions (19% [Experiment 1], 20% [Experiment 2]).

Event Changes Can Lead to Proactive Facilitation in Memory

Both experiments showed that repeating an activity led to overall better correct recall of central features and fewer alternate intrusions than did repeating an initial action sequence and including a changed ending (Figure 4, black points). In Experiment 2, we also replicated the somewhat surprising finding that repeating an activity with a changed feature can lead to *facilitation* rather than interference in overall correct recall (Wahlheim & Zacks, 2019): Recall of central features for changed activities was better than recall of such features for control activities seen only on Day 2 (bottom left panel). Separate models estimating correct Day 2 recall and alternate intrusion probabilities including only Activity Type as a fixed effect (repeated and changed activities in Experiment 1; repeated, control, and changed activities in Experiment 2), indicated significant effects for Day 2 recall [Experiment 1: $\chi^2(1) = 6.59, p = .010$; Experiment 2: $\chi^2(2) = 60.32, p < .001$] and alternate intrusions [Experiment 1: $\chi^2(1) = 28.21, p < .001$; Experiment 2: $\chi^2(2) = 33.58, p < .001$]. For Experiment 2, all pairwise comparisons among the three levels of activity type were significantly different for Day 2 recall (smallest z ratio = 3.43, $p = .002$), whereas the only significant difference for alternate intrusions was between repeated and control activities, z ratio = 1.86, $p = .150$.

Fig. 4.*Cued Recall of Activity Features*

Note. Black points indicate model-estimated probabilities for overall responses. Colored points for conditional cells indicate model-estimated response probabilities for changed activities when changes were recollected (green points), remembered (blue points), or not remembered (red points). Point area differences indicate the relative observation frequencies for those cells. Overall correct recall of Day 2 activity features was better for repeated than changed and for changed than control activities (left panels). Changed activities were recalled best when change was recollected. Intrusions of alternate activity features for changed activities were greater when changes were remembered than when they were not (right panels). Error bars are 95% confidence intervals. Error bars are obscured when the intervals are smaller than the point areas.

Recollecting that Activities had Changed is Associated with Memory Facilitation

To test whether successful updating was associated with recollecting that an activity had changed, we analyzed cued recall performance for changed activities conditionalized on classifications indicating if activities had changed, made just after each cued recall attempt. We created three response classification types for changed activities: *Change Recollected* were accurate classifications with recall of Day 1 features; *Change Remembered* were accurate classifications without correct recall of Day 1 features; and *Change Not Remembered* were inaccurate classifications. Change classification rates were comparable in both experiments: *Recollected* (Experiment 1 = 38%; Experiment 2 = 37%), *Remembered* (Experiment 1 = 19%; Experiment 2 = 18%); and *Not Remembered* (Experiment 1 = 43%; Experiment 2 = 45%).

Correct recall of changed Day 2 features varied depending on how participants classified changed activities at test (Figure 3, green, blue, and red points). In both experiments, models fitted to correct Day 2 recall including Classification as the fixed effect indicated significant effects, smallest $\chi^2(2) = 188.29, p < .001$. Pairwise comparisons indicated that recall was significantly greater when change was recollected (green points) than when it was remembered but not recollected (blue points) or not remembered (red points), smallest z ratio = 11.13, $p < .001$, and that the latter two conditions (blue and red points) were not significantly different, largest z ratio = 0.84, $p = .678$. The results replicate findings showing that enhanced event memory updating for changed activities was associated with change recollection (Garlitch & Wahlheim, 2021; Hermann et al., 2021; Stawarczyk et al., 2020; Wahlheim & Zacks, 2019).

In both experiments, alternate intrusions were most likely when change was remembered but not recollected (blue points) and least likely when change was recollected (green points). The

classification effect was significant in both experiments, smallest $\chi^2(2) = 90.96, p < .001$. All pairwise comparisons were significantly different, smallest z ratio = 3.54, $p = .001$.

Predictive Looking Errors are Associated with Better Event Memory Updating

The previous analyses established that viewers sometimes make mnemonic predictive looking errors when watching Day 2 activities unfold, and that watching a changed activity ending can lead to facilitation, rather than interference, in memory for changed activity features. We hypothesized that these two results are related, such that making a predictive looking error can induce memory updating (cf. Stahl & Feigenson, 2015). To test this hypothesis, we assessed proportions of looking while viewers watched changed activities on Day 2 back-sorted on whether changes were later recollected (Figure 5). We compared activities for which changes were recollected, i.e., that were correctly classified and for which the Day 1 activity feature was recalled (Recollected), to activities for which change was not recollected (Not Recollected). The latter category included activities for which Day 1 features were not recalled, regardless of whether activities were classified as having changed, because recall of Day 2 features in those cells was not significantly different (see Figure 4, left panels, blue and red points).

For changed activities in the Day 2 movie, mnemonic predictive looking errors are looks to alternate objects that the actor had manipulated in the Day 1 movie. Consistent with our hypothesis, Figure 5 (left panels) shows that in both experiments, proportions of looking to alternate objects for changed activities were greater during activities for which viewers subsequently recollected that features had changed (green lines). This was especially true when viewers watched the actor repeat actions from the Day 1 movie in the pre-divergence intervals.

Fig. 5.*Looks to Interest Areas during Changed Activities on Day 2*

Note. Lines indicate model-estimated proportions of looking to interest areas for changed activities during Day 2 movies in Experiments 1 and 2. Green solid lines indicate looking proportions for activities recollected as changed. Purple solid lines indicate looking proportions for activities not recollected as changed. Black dotted lines in Experiment 2 indicate looking proportions for control activities. Viewers looked at alternate objects more during pre-divergence intervals for changed activities subsequently recollected as such, showing that mnemonic predictive looking errors were associated with facilitation in event memory updating.

In both experiments, models fitted to looks to alternate objects with Change Recollection (Recollected vs. Not Recollected [vs. Control in Experiment 2 only]) and Bin as fixed effects showed significant main effects (Table 3, top rows). For Experiment 1, there was also a significant interaction that was characterized using separate models for pre- and post-divergence intervals (Table 3, middle and bottom rows). The proportion of looking to alternate objects was significantly greater for changed activities that were subsequently recollected as such (green line) than those not recollected as such (purple line). This difference was greater in the pre- than post-divergence interval. For Experiment 2, the additional control condition prompted pairwise comparisons to characterize the effect of Change Recollection. Viewers looked to alternate objects more during activities for which changes were subsequently recollected (green line) than during activities for which changes were not recollected (purple line), z ratio = 6.84, $p < .001$, and during control activities (black line), z ratio = 7.45, $p < .001$. This pattern was highly consistent across activities varying in pre-divergence interval length (see Supplemental Material). These results suggest that mnemonic predictive looking errors play a critical role in the facilitation in memory updating that occurred when changes were recollected.

Proportions of looking to target objects in the Day 2 movie (Figure 5, right panels) were also compared. These analyses tested the hypothesis that viewers should not show greater predictive looking associated with subsequent change recollection because target objects had not been contacted in the Day 1 movie. Thus, mnemonic predictions should not guide the eyes to look earlier and more often to objects that the actor had not manipulated. Models comparable to those for alternate objects confirmed this prediction (Table 4). In Experiment 1, neither the effect of Change Recollection, nor Change Recollection $\times$ Bin interaction was significant. In Experiment 2, there was a significant effect of Change Recollection, but pairwise comparisons

indicated no significant differences among conditions, smallest z ratio = 2.31, $p = .054$. Overall, these results are consistent with the hypothesis that memory only predictively guides the eyes to previous action targets. Finally, we also found that overall correct recall of changed activity features from the Day 2 movie was associated with greater proportions of looking to alternate objects in the pre-divergence interval (see Supplemental Material).

Discussion

Two experiments examined the role of mnemonic prediction error in event memory updating by assessing the association between predictive looking and memory for changed activities. Predictive looking to objects an actor had contacted was associated with facilitated memory for changed activity features. This was shown by an association between memory for earlier-contacted objects and looking to those objects during repeated actions as well as better memory for changed objects and recollection of the change. These results suggest that mnemonic prediction errors partly contribute to event memory updating for dynamic everyday actions.

The present results converge with action observation studies showing that viewers look ahead when performing and watching everyday actions (Eisenberg et al., 2018; Hayhoe et al., 2003; Land & McLeod, 2000). These results replicated findings of predictive looking during movies of everyday activities (Eisenberg et al., 2018), as viewers looked increasingly more to target objects when watching Day 1 movies. These findings support the perspective that viewers use motor knowledge to predict action goals (Flanagan & Johansson, 2003). The present results also converged with findings from simplified trial-based designs showing that viewers look ahead to earlier-watched actions (Cannon et al., 2012; Falck-Ytter et al., 2006; Gredebäck et al., 2018). Specifically, when watching the Day 2 movie, viewers looked more to objects that had been contacted in the Day 1 movie. This was true for activities that repeated completely and

those included only repetitions of the initial action sequence in the pre-divergence interval, suggesting that memory guided action predictions during activity viewing.

The present study also showed that mnemonic prediction errors enhanced adults' new learning. These results extend on action observation studies with infants and children showing that prediction errors invite active learning (Gredebäck et al., 2018; Juvrud et al., 2019; Stahl & Feigenson, 2015). Viewers in the preset study looked earlier and more often to repeated pre-divergence actions and changed post-divergence actions, suggesting that mnemonic prediction errors stimulated encoding of changed features. This view was also supported by the finding that change recollection, which was strongly associated with facilitated memory updating, was also associated with predictive looking to earlier-contacted objects. The present results therefore show that mnemonic prediction errors facilitate encoding and retrieval of everyday events.

The role of prediction error in event memory updating has been studied in various ways, leading to different outcomes and theoretical perspectives. Some theories assume that prediction errors impair memory when unfulfilled expectations lead to weakened representations of expected events (Kim et al., 2014) or increases in intrusion errors (Sinclair & Barense, 2018). These views are similar to models proposing that reactivating existing memories prior to new events destabilizes those memories (Exton-McGuinness et al., 2015; Lee et al., 2017). Other theories propose that repeating event features triggers retrieval of existing memories, leading to predictions that associated stimuli will follow. However, when changes occur, prediction errors stimulate encoding (Antony et al., 2020; Bein et al., 2020; Chen et al., 2015; Greve et al., 2017; Wahlheim & Zacks, 2019). The present findings are consistent with the latter perspective, with evidence from looking proportions associated with error-driven updating converging with results

showing that neural reactivation of dynamic naturalistic events is associated with improved encoding of changed activity features (Stawarczyk et al., 2020).

One potential mechanism for the error-driven updating observed here is integrative encoding of event representations. Interference theories predict that event changes should impair memory (Anderson & Neely, 1996). However, there is mounting evidence that interference is mitigated when prior events are retrieved and integrated with new events (Chanales et al., 2019; Wahlheim & Jacoby, 2013). This integration may be mediated partly by medial temporal structures that are biased towards encode states by mnemonic prediction errors (Bein et al., 2020). Another mechanism that could operate simultaneously is integrative encoding of eye movement shifts from first- to second-contacted objects after prediction errors. This is consistent with the view that eye movements can become embedded in and support subsequent memory (Ryan et al., 2020; Wynn et al., 2019). Such gaze-enhanced encoding could be examined by restricting eye movements (e.g., Henderson et al., 2005) to determine if preventing shifts between objects impairs memory for recently contacted objects. Finally, although we have interpreted the present looking patterns as showing that updating benefited from retrieval of activities before changes appeared, it may have also benefitted from retrospective comparisons of activity features occurring after changes appeared. Research is needed to understand how the timing of retrieval-and-comparison processes affects subsequent memory updating.

Although the current paradigm is more naturalistic than many other memory updating paradigms, some features of the task limit its generalizability. Participants watched the actor perform everyday actions in a distraction-limited environment, which differs from everyday life in which viewing goals are dynamic and susceptible to distractions. Also, the present movies included an unfamiliar actor with specific demographic characteristics, which differs from

everyday life because viewers also observe actions of actors of varying familiarity from various backgrounds. Future studies should manipulate these variables to better assess the conditions under which mnemonic prediction errors are associated with facilitation in memory updating.

In summary, while watching an actor perform naturalistic everyday actions, viewers looked ahead to earlier-contacted objects before action changes were perceived. This predictive looking occurred more for actions subsequently recollected to have changed, and this was associated with better memory updating for changed actions. These results support the view that mnemonic prediction errors play a critical role in event memory updating by promoting more effective encoding and retrieval of changed activity features.

Open Practices Statement

Neither of the experiments reported in this article was formally preregistered. De-identified data supporting the findings of this study, the code written to analyze these data, and the experimental stimuli are available in the Open Science Framework repository:

	Bin	9022.16	19	< .001
	Change Recollection $\times$ Bin	24.37	38	= .958

Note. The model results correspond to the data displayed in Figure 5 (right panels). For Experiment 2, note that the Change Recollection variable include both changed activities conditionalized on change recollection and control activities that were not conditionalized on change recollection.

Supplemental Material

Task Instructions: Experiment 1

Instructions for Session 1

[**Not shown to participants:** The paragraph below appeared before each of eight scenes showing sequences of morning, work, afternoon, and evening activities performed on the first and second days. Before each movie clip, the time of the **SCENE** (morning, work, afternoon, or evening) and the **DAY** (Day 1 or Day 2) of the activities was updated to correspond with the activities that followed. (Note this method was also used in the Experiment 2 instructions below.)]

Shown to participants before each scene:

For this task, you will watch movies of two days in a woman's life. You will see her perform activities during four parts of each day: morning, work, afternoon, and evening. The clip will show her **SCENE** on **DAY**. Please pay attention and watch the clip carefully. Your memory for aspects of her activities will be tested later. Press the blue button when you're ready to begin.

Instructions for Session 2

In this part of the experiment, you will be asked to recall details from the activities you watched the actor perform on the second "Day." For each question, you will first be asked to type a response in a box below. After you have typed your response, press ENTER.

Here, we are also interested in your ability to remember which activities changed from Day 1 to Day 2. When you watched the actor perform activities, she performed some activities in the exact same manner on both days, whereas she changed how she performed another set of activities from the first to second day. An example of a changed activity would be if the actor had styled her hair with a **COMB** on the first day and with a **BRUSH** on the second day.

After recalling details from each activity, you will be asked whether the manner in which she performed the activity changed from Day 1 to Day 2. Press the "1" button to respond "Yes" and the "2" button to respond "No." When you respond "Yes" that you remember the activity changing from Day 1 to Day 2, you will be asked to report how she originally performed the activity on Day 1. Please type your response in the box and press ENTER.

Task Instructions: Experiment 2

Instructions for Session 1

Shown to participants at the beginning of the experiment:

The purpose of this study is to investigate how people understand everyday events. We will be using an eye-tracking camera to record your eye movements while watching movies of an actor performing daily life activities and after that we'll ask you to answer some questions about these movies. Also, the experiment will be in two sessions, one now and one next week. The first session will last approximately 1 hour and 30 minutes and the second session will last approximately 30 minutes.

Shown to participants before each scene:

For this task, you will watch movies of two days in a woman's life. You will see her perform activities in four parts of each day: morning work, afternoon, and evening. The clip will show her **SCENE** on **DAY**. [Not shown to participants: As for Experiment 1, the description of the upcoming movie clip (in red font here) was updated before each scene.] Please pay attention and watch the clip carefully. Your memory for aspects of her activities will be tested later.

Instructions for Session 2

In this part of the experiment, you will be asked to recall the activities you watched the actor perform on the second "Day." For each question, you will first be asked to type a response in a box below. After you have typed your response, press ENTER.

Here, we are also interested in your ability to remember which activities changed from Day 1 to Day 2. When you watched the actor perform both activities, she performed some activities in the exact same manner on both days, she changed how she performed another set of activities from the first to second day, and she only performed some activities on the second day. An example of a changed activity would be if the actor had styled her hair with a COMB on the first day and with a BRUSH on the second day.

After recalling details from each activity, you will be asked whether the manner in which she performed the activity changed from Day 1 to Day 2. Press the "1" button to respond "Repeated exactly", the "2" button to respond "Changed feature", and the "3" button to respond "Only shown on Day 2". When you respond "2" ("Changed feature") that you remember the activity changing from Day 1 to Day 2, you will be asked to report how she originally performed the activity on Day 1. Please type your response in the box and press ENTER.

Additional Analyses

Memory-based Predictive Looking Errors are Associated with Better Day 2 Recall

Correct recall of changed activities after a one-week delay was associated with more memory-based predictive looking in the pre-divergence interval on Day 2 (see Figure S1 below). To test the statistical significance of this effect, we fitted mixed effects models with subject and items as random effects and Recall Accuracy (Correct vs. Incorrect) and Bin as fixed effects separately for alternate and target objects (for results, see Table S1 below). The models for alternate objects (left panels) indicated significant effects of Recall Accuracy showing more looking for subsequently correct than incorrect recalls. There were significant effects of Bin and no significant interactions. The models for target objects (right panels) showed comparable looking for later correct and incorrect recalls.

Fig. S1.

Estimated Proportions of Looking in Interest Areas for Changed Activities on Day 2

Note. Model-estimated proportions of looking to interest areas for changed activities on Day 2 as a function of Recall Accuracy (Correct [blue lines] vs. Incorrect [red lines]) and Bin for alternate (left panel) and target (right panel) objects.

Table S1

Looking Model Results for Changed Activities conditionalized on Day 2 Recall Accuracy for Each Object Type

Object	Effect	Experiment 1			Experiment 2		
		χ^2	df	p	χ^2	df	p
Alternate	Accuracy	6.76	1	= .009	8.62	1	= .003
	Bin	649.89	19	< .001	1093.18	19	< .001
	Accuracy $\times$ Bin	12.39	19	= .868	12.35	19	= .870
Target	Accuracy	0.08	1	= .778	5.87	1	= .015
	Bin	2938.74	19	< .001	6182.19	19	< .001
	Accuracy $\times$ Bin	13.19	19	= .829	5.99	19	= .998

Note. The model results correspond to the data displayed in Figure S1.

Pupil Area Increased as Activities Unfolded

We conducted exploratory analyses of pupil area for each activity type on both days (see Figure S2 below). Pupil data were first normalized for each participant by removing blinks and then identifying the 2.5th and 97.5th percentile of pupil area for each participant. To control for individual differences in eye size, pupil measurements were rescaled for each participant by subtracting off the 2.5th percentile and dividing by the difference between the 97.5th percentile and the 2.5th percentile, such that values at the 2.5th percentile mapped to zero and values at the 97.5th percentile mapped to one. We then fitted mixed effects models with subjects and activities (items) as random intercept effects and Activity Type (Repeated vs. Changed), Day and Bin as fixed effects in both experiments (for results, see Table S2 below). We also fitted a separate model to Control activities alone in Experiment 2.

The models for both experiments indicated significant effects for all except the Activity $\times$ Bin and Day $\times$ Activity $\times$ Bin interactions. The effects of Day indicated larger pupil areas on Day 2 than Day 1 in Experiment 1 and the reverse in Experiment 2. For both experiments, the Day $\times$ Bin interactions indicated that pupil areas increased as activities unfolded to a greater extent on Day 2 than Day 1. The Day $\times$ Activity interactions indicated that area differences between days were greater for Changed than Repeated activities; however, the direction of these area differences was opposite in each experiment (see effects of Day). For Control activities on Day 2 in Experiment 2, a significant Bin effect, $\chi^2(1) = 244.03, p < .001$, indicated that pupil area increased as activities unfolded.

Fig. S2.*Estimated Pupil Area for All Activity Types*

Note. Model-estimated normalized pupil areas as a function of Day, Activity Type, and Time Bin.

Table S2*Pupil Area Model Results for Repeated and Changed Activities*

Experiment	Effect	χ^2	<i>df</i>	<i>p</i>
Experiment 1	Day	275.59	1	< .001
	Activity	68.77	1	< .001
	Bin	1057.52	19	< .001
	Day $\times$ Activity	17.49	1	< .001
	Day $\times$ Bin	98.81	19	< .001
	Activity $\times$ Bin	14.06	19	= .780
	Day $\times$ Activity $\times$ Bin	7.14	19	= .993
Experiment 2	Day	31.54	1	< .001
	Activity	20.07	1	< .001
	Bin	1839.74	19	< .001
	Day $\times$ Activity	9.71	1	= .002
	Day $\times$ Bin	83.53	19	< .001
	Activity $\times$ Bin	2.47	19	= .999
	Day $\times$ Activity $\times$ Bin	2.41	19	= .999

Note. The model results correspond to the data displayed in Figure S2.

Pupil Area Differences for Changed Activities Conditionalized on Change Recollection

We also conducted exploratory analyses of normalized pupil area for changed activities on both days conditionalized on change recollection (see Figure S3 below). We examined these effects using mixed effects models with subject and items as random effects and Change Recollection, Day, and Bin as fixed effects (for results, see Table S3 below). For both experiments, the models indicated significant effects for all except the Change Recollection $\times$ Bin and Day $\times$ Change Recollection $\times$ Bin interactions, and the Day $\times$ Change Recollection interaction in Experiment 2. The effects of Day indicated larger pupil areas on Day 2 than Day 1 in Experiment 1 and the reverse in Experiment 2. For both experiments, the Day $\times$ Bin interactions indicated that pupil areas increased as activities unfolded to a greater extent on Day 2 than Day 1. The Day $\times$ Change Recollection interaction in Experiment 1 indicated that pupil areas on Day 1 were larger when changed activities were not later recollected as such, whereas pupil areas on Day 2 were larger when changed activities were recollected as such. This effect did not replicate in Experiment 2.

Fig. S3.

Estimated Pupil Area for Changed Activities Conditionalized on Change Recollection

Note. Model-estimated proportions of looking to interest areas for changed activities as a function of Change Recollection (Recollected [green lines] vs. Not Recollected [purple lines]) and Time Bin.

Table S3*Pupil Area Model Results for Changed Activities Conditionalized on Change Recollection*

Experiment	Effect	χ^2	<i>df</i>	<i>p</i>
Experiment 1	Day	216.50	1	< .001
	Change Recollection	0.06	1	= .802
	Bin	641.28	19	< .001
	Day × Change Recollection	75.30	1	< .001
	Day × Bin	58.77	19	< .001
	Change Recollection × Bin	14.85	19	= .732
	Day × Change Recollection × Bin	8.39	19	= .982
Experiment 2	Day	43.08	1	< .001
	Change Recollection	9.54	1	= .002
	Bin	1178.51	19	< .001
	Day × Change Recollection	0.50	1	= .481
	Day × Bin	59.68	19	< .001
	Change Recollection × Bin	35.90	19	= .011
	Day × Change Recollection × Bin	18.59	19	= .483

Note. The model results correspond to the data displayed in Figure S3.

Interval Length and Proportions of Looks to Interest Areas

We determined the consistency of key looking proportion effects reported in the main manuscript across activities (items) by examining such effects at varying interval lengths. To test for interactions with interval length, we divided pre- and post-divergence portions of activities into three equal groups (tertiles) based on interval length. Then we fitted mixed effects models with subjects and activities as random intercept effects and experimental variables from the analyses reported in the main manuscript, including interval length tertile (Tertile), as fixed effects. We examined interval length effects separately for pre- and post-divergence intervals because activities often comprised interval lengths from different tertiles. When comparing the analyses reported here with those reported in the main manuscript, note that the latter analyses did not require separating pre- and post-divergence intervals, thus the effects are not directly comparable. To foreshadow, these analyses showed general consistency in the qualitative patterns of interest. However, they did indicate some quantitative differences in the magnitude of the effects of interest as a function of the length of the pre- and post-divergence intervals. Table S4 displays the descriptive statistics for interval length tertiles.

Table S4*Pre- and Post-Divergence Interval Lengths as a Function of Tertile*

Interval	Tertile	Interval Length (ms)			
		<i>M</i>	<i>SD</i>	Minimum	Maximum
Pre-Divergence	1	1987	1165	100	3470
	2	4190	608	3500	5680
	3	9271	2953	5710	16920
Post-Divergence	1	276	52	140	340
	2	436	57	370	570
	3	2444	3368	600	13250

Changed Activities on Day 2 (Conditionalized): Pre-Divergence Intervals. The effect of primary theoretical interest in this study was the finding that viewers looked more at alternate objects during the pre-divergence interval of the Day 2 movie for changed activities that were subsequently recollected as such (see Figure 5 in main manuscript). We examined the consistency of this effect in across interval lengths (Figure S4, left panels) using models with Change Recollection, Bin, and Tertile as fixed effects (for results, see Table S5, top rows). The models for looking proportions to alternate objects indicated mostly consistent effects in both experiments. Both models indicated a significant effect of Change Recollection showing that the proportion of looking was greater for changed activities when they were later recollected as such. Importantly, this effect did not significantly interact with Tertile in either experiment. Together,

these results show that the effect of primary interest suggesting that mnemonic predictive looking errors contribute to event memory updating was quite consistent across interval lengths.

The models for looking proportion to target objects indicated that the effects were a bit less consistent across experiments. There was an effect of Change Recollection in Experiment 1 indicating fewer looks during changed activities that were later recollected as such. Although that effect did not replicate in Experiment 2, a significant Change Recollection $\times$ Tertile interaction indicated no significant differences in looking proportions for the second and third tertiles, largest z ratio = 1.57, p = .117. However, the model did indicate significantly more looks during changed activities later recollected as such in the first tertile, z ratio = 3.48, p < .001. Although there is not an immediately clear explanation for these inconsistencies, it is most important to note that the qualitative patterns of looks to target objects differed from those for looks to alternate objects. This difference bolsters the interpretation that anticipatory looks to alternate objects contact in the first movie reflected a greater reliance on mnemonic processes.

Changed Activities on Day 2 (Conditionalized): Post-Divergence Intervals. We also examined the consistency of looking proportions to both objects in the post-divergence interval across activity interval lengths (Figure 4, right panels). The models for alternate objects (for results, see Table S6, top rows) both indicated significant effects of Change Recollection and Bin that were qualified by significant interactions with Tertile. The Change Recollection $\times$ Tertile interactions indicated qualitatively different patterns across experiments. In Experiment 1, there were significantly more looks when changed activities were recollected as such in the second tertile, z ratio = 4.17, p < .001, and no significant difference in looks depending on change recollection in the other tertiles, largest z ratio = 1.43, p = .153. In Experiment 2, there were significantly more looks when changed activities were recollected as such in the first and third

tertiles, smallest z ratio = 2.30, $p = .022$, and no significant difference in the second tertile, z ratio = 0.46, $p = .647$. The Bin $\times$ Tertile interactions in both experiments indicated that the greatest decrease in looks across bins occurred for activity lengths in the second tertile.

The models for target objects (for results, see Table S6, bottom rows) both indicated a significant Bin $\times$ Tertile interaction showing the least increase in looking across bins for activity lengths in the first tertile. The model in Experiment 2 also indicated a significant Change Recollection $\times$ Tertile interaction showing significantly more looks for changed activities recollected as such in the second tertile, z ratio = 3.35, $p < .001$, and no significant differences depending on change recollection in the first and third tertiles, largest z ratio = 1.65, $p = .099$.

Fig. S4.

Estimated Proportions of Looking in Interest Areas for Changed Activities on Day 2

Conditionalized on Change Recollection as a Function of Interval Tertile

Note. Model-estimated proportions of looking to interest areas for changed activities as a function of Change Recollection (Recollected [green lines] vs. Not Recollected [purple lines]) and Time Bin.

Table S5

Looking Model Results for Changed Activities on Day 2 Conditionalized on Change Recollection in Pre-Divergence Intervals for Each Object Type as a Function of Interval Tertile

Object	Experiment	Effect	χ^2	df	p
Alternate	Experiment 1	Change Recollection	48.13	1	< .001
		Bin	14.99	9	= .091
		Tertile	135.24	2	< .001
		Change Recollection $\times$ Bin	2.71	9	= .975
		Change Recollection $\times$ Tertile	1.88	2	= .390

		Bin	552.42	9	< .001
		Tertile	47.81	2	< .001
		Change Recollection $\times$ Bin	7.07	9	= .630
		Change Recollection $\times$ Tertile	10.31	2	= .006
		Bin $\times$ Tertile	126.94	18	< .001
		Change Recollection $\times$ Bin $\times$ Tertile	6.90	18	= .991

Note. The model results correspond to the data displayed in Figure S4 (right panels).

Repeated Activities: Pre-Divergence Intervals. For completeness, we also examined the consistency of looking proportions to each object on both days for all repeated and changed activity types. We examined the consistency of effects across interval lengths using models with Day, Bin, and Tertile as fixed effects for each object type. The models for looking to target objects in repeated activities during pre-divergence intervals (Figure S5, left panels) showed similar patterns in both experiments (for results, see Table S6, top rows): There were significantly more looks on Day 2 than Day 1, in the later than earlier time bins, and in the second than first and third tertiles, smallest z ratio = 2.66, $p = .022$. The significant Bin $\times$ Tertile interactions indicated that looks increased from earlier to later bins most in the third tertile in Experiment 1 and least in the second tertile in Experiment 2. A significant Day $\times$ Tertile interaction that only emerged in Experiment 2 indicated that the effect showing more looks on Day 2 than Day 1 was significant for activities in the first and third tertile, smallest z ratio = 2.94, $p = .003$, but was not significant for activities in the second tertile, z ratio = 1.24, $p = .214$.

The models for looking to alternate objects in repeated activities during pre-divergence intervals (Figure S5, left panels) showed similar patterns in both experiments (for results, see Table S6, bottom rows). The significant effects of Bin showed unsystematic fluctuation in looking proportions as the activities unfolded. In addition, the significant effects of Tertile indicated significantly more looking to activities in the first than second and third tertiles, smallest z ratio = 3.77, $p < .001$. A significant Bin $\times$ Tertile interaction that only emerged in Experiment 1 indicated that there were qualitative differences in looks over times across interval lengths, but there was no obvious systematicity in such differences. Also, a significant Day $\times$ Tertile interaction that only emerged in Experiment 2 indicated significantly more looks on Day

2 than Day 1 during activities in the second tertile, z ratio = 4.78, $p < .001$, and no significant differences in looks during activities in the first and third tertiles, largest z ratio = 1.83, $p = .067$.

Repeated Activities: Post-Divergence Intervals. The models for looking to target objects in repeated activities during post-divergence intervals (Figure S5, right panels) showed similar patterns in both experiments (for results, see Table S7, top rows). The significant Day $\times$ Tertile interactions indicated that there were significantly more looks on Day 2 than Day 1 in Experiment 1 during activities in the second and third tertiles, smallest z ratio = 3.86, $p < .001$, and in Experiment 2 during the activities in the first and second tertiles, smallest z ratio = 3.73, $p < .001$. There were no significant looking differences during activities in the other intervals, largest z ratio = 1.43, $p = .152$. The significant Bin $\times$ Tertile interactions both indicated that looks to target objects increased the least during activities in the first tertile. A significant Day $\times$ Bin $\times$ Tertile interaction that only emerged in Experiment 2 indicated that magnitude of looking differences between days diminished greatly as activities unfolded only in the second tertile. Note that a similar pattern emerged in Experiment 1, but the corresponding interaction was not significant.

The models for looking to alternate objects in repeated activities during post-divergence intervals (Figure S5, right panels) showed similar patterns in both experiments (for results, see Table S7, bottom rows). The significant effects of Day indicated significantly fewer looks when viewing the Day 2 than Day 1 movie; however, a significant Day $\times$ Tertile interaction in Experiment 2 indicated that these differences were significant in all except the activities in the third tertile, z ratio = 1.37, $p = .172$. The significant effects of Bin indicated that looks to alternate objects decreased as activities unfolded, and these effects were qualified by significant Bin $\times$ Tertile interactions showing that looks decreased the most during activities in the second

tertile. The significant effects of Tertile indicated that there were significantly more looks to alternate objects in Experiment 1 during activities in the third than both the first and second tertiles, smallest z ratio = 3.05, $p < .01$, and in Experiment 2 during activities in the third than first tertile, z ratio = 4.04, $p < .001$ (looking during activities in the second tertile was not significantly different than during the other tertiles, largest z ratio = 2.21, $p = .070$).

Fig. S5.

Estimated Proportions of Looking to Target and Alternate Objects During Movie Viewing for Repeated Activities as a Function of Interval Tertile

Note. Model-estimated proportions of looking in interest areas including target and alternate objects during interest periods for critical activities. Orange dashed lines indicate looking proportions during Day 1 movie viewing. Black solid lines indicate looking proportions during Day 2 movie viewing.

Table S6

Looking Model Results for Repeated Activities in Pre-Divergence Intervals for Each Object Type on Each Day as a Function of Interval Tertile

Object	Experiment	Effect	χ^2	df	p

	Experiment 2	Day	52.34	1	< .001
		Bin	355.66	9	< .001
		Tertile	50.28	2	< .001
		Day $\times$ Bin	4.40	9	= .883
		Day $\times$ Tertile	22.79	2	< .001
		Bin $\times$ Tertile	39.02	18	= .003
		Day $\times$ Bin $\times$ Tertile	40.67	18	= .002
Alternate	Experiment 1	Day	17.62	1	< .001
		Bin	101.49	9	< .001
		Tertile	12.95	2	= .002
		Day $\times$ Bin	4.11	9	= .904
		Day $\times$ Tertile	0.33	2	= .847
		Bin $\times$ Tertile	49.68	18	< .001
		Day $\times$ Bin $\times$ Tertile	5.46	18	= .998
	Experiment 2	Day	32.30	1	< .001
		Bin	128.09	9	< .001
		Tertile	16.48	2	< .001
		Day $\times$ Bin	6.26	9	= .713
		Day $\times$ Tertile	12.95	2	= .002
		Bin $\times$ Tertile	37.02	18	= .005
		Day $\times$ Bin $\times$ Tertile	19.09	18	= .387

Note. The model results correspond to the data displayed in Figure S5 (right panels).

Changed Activities: Pre-Divergence Intervals. The models for looking to target objects in changed activities during pre-divergence intervals (Figure S6, left panels) showed similar patterns in both experiments (for results, see Table S8, top rows). The significant effects of Bin indicated that looks generally increased significantly from early to late bins. The significant Bin $\times$ Tertile interactions qualifying these effects showed that, in Experiment 1, looks increased the least in the second tertile and, in Experiment 2, looks increased the most in the first tertile. The significant effects of Tertile indicated that the most looks occurred in the second tertile and the least looks occurred in the first tertile in both experiments. In Experiment 1, looks in the second and third tertiles were not significantly different, z ratio = 1.93, p = .13, whereas in Experiment 2, looks were significantly greater in the second than third tertile, z ratio = 5.82, p < .001. The significant Day $\times$ Tertile interaction in Experiment 2 indicated that there were significantly more looks in the Day 1 than Day 2 movie during activities in the first tertile, z ratio = 2.14, p = .032, and in the Day 2 than Day 1 movie during activities in the second tertile, z ratio = 2.75, p = .006. There was no significant difference in looks between movies during activities in the third tertile, z ratio = 1.17, p = .240.

The models for looking to alternate objects in changed activities during pre-divergence intervals (Figure S6, left panels) showed similar patterns in both experiments (for results, see Table S8, bottom rows). The significant Day $\times$ Tertile interactions indicated significant more looks in the Day 2 than Day 1 movie in the first and third tertiles, smallest z ratio = 2.00, p = .046. The significant Bin $\times$ Tertile interactions indicated idiosyncratic fluctuations in looking as activities unfolded across tertiles that were qualitatively similar in both experiments.

Changed Activities: Post-Divergence Intervals. The models for looking to target objects in changed activities during post-divergence intervals (Figure S6, right panels) showed

similar patterns in both experiments (for results, see Table S9, top rows). The significant Day $\times$ Tertile interactions in both experiments indicated that there were significantly more looks in the Day 2 than Day 1 movie mostly in the second tertile, and that in Experiment 2, there was no significant difference in the proportion of looks in each movie during activities in third tertile, z ratio = 0.81, $p = .416$. The significant Bin $\times$ Tertile interactions indicated that the general increase was least during activities in the first tertile.

The models for looking to alternate objects in changed activities during post-divergence intervals (Figure S6, right panels) showed similar patterns in both experiments (for results, see Table S9, bottom rows). The significant Bin $\times$ Tertile interactions showed that the general decrease in looks from the early to late times bins was greatest in the second tertile in both experiments. The significant effect of Day in Experiment 2 indicated that there were significant more looks in the Day 2 than Day 1 movie. In contrast, the significant Day $\times$ Tertile interaction that emerged in Experiment 1 indicated that there were significantly more looks in the Day 1 than Day 2 movie in the second tertile, z ratio = 6.61, $p < .001$, and no significant difference in looks between movies in the other tertiles, largest z ratio = 0.68, $p = .497$.

Fig. S6.

Estimated Proportions of Looking to Target and Alternate Objects During Movie Viewing for Changed Activities as a Function of Interval Tertile

Note. Model-estimated proportions of looking in interest areas including target and alternate objects during interest periods for critical activities. Orange dashed lines indicate looking proportions during Day 1 movie viewing. Black solid lines indicate looking proportions during Day 2 movie viewing.

Table S8

Looking Model Results for Changed Activities in Pre-Divergence Intervals for Each Object Type on Each Day as a Function of Interval Tertile

Object	Experiment	Effect	χ^2	df	p
Target	Experiment 1	Day	3.81	1	= .051
		Bin	62.99	9	< .001
		Tertile	227.34	2	< .001
		Day $\times$ Bin	14.65	9	= .101
		Day $\times$ Tertile	2.08	2	= .353
		Bin $\times$ Tertile	57.81	18	< .001
		Day $\times$ Bin $\times$ Tertile	13.42	18	= .766
	Experiment 2	Day	0.11	1	= .743
		Bin	220.17	9	< .001
		Tertile	502.80	2	< .001
		Day $\times$ Bin	6.38	9	= .701
		Day $\times$ Tertile	13.41	2	= .001
		Bin $\times$ Tertile	70.08	18	< .001
		Day $\times$ Bin $\times$ Tertile	8.21	18	= .975
Alternate	Experiment 1	Day	37.34	1	< .001
		Bin	18.07	9	= .034
		Tertile	207.86	2	< .001
		Day $\times$ Bin	2.75	9	= .973
		Day $\times$ Tertile	21.94	2	< .001
		Bin $\times$ Tertile	29.35	18	= .044
		Day $\times$ Bin $\times$ Tertile	4.35	18	= .999
	Experiment 2	Day	31.21	1	< .001
		Bin	52.92	9	< .001
		Tertile	373.86	2	< .001
		Day $\times$ Bin	6.14	9	= .726
		Day $\times$ Tertile	28.97	2	< .001
		Bin $\times$ Tertile	54.00	18	< .001
		Day $\times$ Bin $\times$ Tertile	10.49	18	= .915

Note. The model results correspond to the data displayed in Figure S6 (left panels).

Table S9

Looking Model Results for Changed Activities in Post-Divergence Intervals for Each Object Type on Each Day as a Function of Interval Tertile

Object	Experiment	Effect	χ^2	df	p
Target	Experiment 1	Day	81.32	1	< .001
		Bin	456.48	9	< .001
		Tertile	19.02	2	< .001
		Day $\times$ Bin	1.76	9	= .995
		Day $\times$ Tertile	47.50	2	< .001
