Abstract

Two fundamental issues in memory research concern when later experiences strengthen or weaken initial memories and when the two memories become linked or remain independent. A promising candidate for explaining these issues is semantic relatedness. Here, across five paired associate learning experiments (N=1000), we systematically varied the semantic relatedness between initial and later cues, initial and later targets, or both. We found that learning retroactively benefited long-term memory performance for semantically related words (versus unshown control words), and these benefits increased as a function of relatedness. Critically, memory dependence between initial and later pairs also increased with relatedness, suggesting that pre-existing semantic relationships promote interdependence for memories formed across episodes. We also found that modest retroactive benefits, but not interdependencies, emerged when subjects learned via studying rather than practice testing. These findings demonstrate that semantic relatedness during new learning retroactively strengthens old associations while scaffolding new ones into well-fortified memory traces.

When a novice bartender is first learning to make cocktails, they are faced with an intimidating repertoire of closely related recipes. For example, they may begin by learning that a “Manhattan” is made with *sweet vermouth*. Later, they may learn that a “martini” is made with *dry vermouth*. These memories are not necessarily independent: the bartender may find that learning to make the martini has retroactively affected their memory of the Manhattan, either by weakening it, a phenomenon known as retroactive interference (*RI*), or by strengthening it, a phenomenon known as retroactive facilitation (*RF*). What properties of the earlier and later memories determine this relationship?

Here, we evaluate an over 70-year-old proposal by Osgood (1) that this relationship depends on *semantic relatedness*. In building up to this proposal, we will consider three broad possibilities. The first possibility is that relatedness has no effect on episodic memory. A second possibility is that relatedness across experiences introduces interference between memories. Third, relatedness could trigger reminders of prior information during new learning, causing the rehearsal and strengthening of prior memories.

In order for the first (null) account to be correct, memories must be formed distinctly, and processes operating during both encoding and retrieval must be able to accurately pinpoint and isolate memories without any residual effects or dependence on semantics. We consider this account helpful to consider because these processes clearly *are* affected by semantic relatedness, as many decades of research have shown. For instance, semantic relatedness improves memory when both items of a paired associate are related (2–4), it provides an organizational scaffold for clustering responses during free recall (5–8), and it can create false memories for highly related associate words (9, 10). In favor of the second (interference) account, pairing a single retrieval cue with multiple target responses could benefit from greater semantic differences between the targets, allowing for easier dissociation between them (11). Indeed, increasing relatedness between tasks in some paradigms can increase interference (12–14) and/or the rate of intruding material from one task to the other (15–19). Finally, in favor of the third (strengthening) account, there is evidence that we are not always passive during new learning: sometimes we “think back” to, and thereby reactivate, prior experiences (20). These events, called recursive reminders, can occur when subjects are given explicit instructions or cues as reminders (21–23), or – more relevantly here – they can occur spontaneously when information is related (24, 25). Moreover, recursive reminders seem to create interdependence between old and new information, with preserved information about the temporal order of learning rather than source confusion and negative competition between the traces (20, 26–28). The recursive reminders account therefore predicts that semantic relatedness would promote *RF* and interdependence among memory traces. Altogether, the first account is clearly incorrect, but when and how strongly the countervailing forces of *RI* and *RF* from the latter accounts operate remains a central puzzle.

In examining these accounts more deeply, we will focus on a range of findings from experimental paradigms featuring associations between cues (*A*) and targets (*B*). In these paradigms, simply practicing the associations (i.e., seeing the cues paired with the same targets) ubiquitously (and obviously) produces *RF* of the original *A-B* association. One of the most studied deviations from this involves linking identical cues (*A*) with new targets (*D*) after *A-B* learning (29, 30). This paradigm is canonically referred to as *A-B, A-D* learning, and we will call it Δ Target learning because it involves a change in the target. Δ Target learning typically causes *RI* for the original *A-B* memory, likely due to competition between the target responses during retrieval (12, 31). However, this *RI* effect is known to be sensitive to the relationship between the old target (*B*) and new target (*D*), as *RI* generally decreases from substantial to near-absent when *B* and *D* are semantically related (16, 18, 30, 32–37). In other paradigms, interference can become reduced by encouraging subjects to integrate the two interfering pieces of information (38–41), suggesting that high semantic relatedness may reduce *RI* by making the related memories interdependent. These findings suggest that *RI* generally occurs

when a cue is linked with competing target responses, but that increasing relatedness can reduce or overcome these effects, likely due to recursive reminders.

The idea that competition between targets at retrieval causes RI makes a different prediction for lists with identical targets but new cues. Under such A-B, C-B learning conditions, which we call Δ Cue learning, little to no RI occurs (42–44). In fact, when targets are identical and old and new cues are semantically related, RF occurs (45, 46). However, the level of relatedness may be more modest in this case, exposing a contrast between the role of cues and targets. Finally, changing both cues and targets at once, canonically referred to as A-B, C-D learning that we will call Δ Both learning, generally results in a completely different learning event (i.e., neither RI nor RF). Studies bearing some level of relationship to the original A-B pair are scant. However, there have been cases where *either* the new cue was semantically related to the old cue but the targets were unrelated, the new target was semantically related to the old target but the cues were unrelated, or both new cues and targets shared some modest level of relatedness with the old ones; in each of these cases, RI for the original A-B association has been observed when testing occurred after short retention intervals (on the order of minutes) (13, 46–48). However, to our knowledge, no study has investigated longer-term memory in cases where the new cues and targets were both highly related to the old ones.

To conceptualize this complex array of RI/RF effects, Osgood proposed three continuous directions along which relatedness influences memory (49, 50). First, when cue identity is held constant, he reasoned that there must be some point along the Δ Target line between an unrelated target and an identical target (i.e., from A-B, A-D to A-B, A-B) at which RI shifts to RF. Second, holding the unrelated target constant and manipulating the cue from an identical cue to an unrelated cue (i.e., from A-B, A-D to A-B, C-D), he reasoned that RI should disappear: the pair becomes an entirely new relation. Third, when the target is identical, Osgood noted that RI generally does not occur and drew a Δ Cue line from unrelated, which produced no memory change, to maximum RF at identity (i.e., from A-B, C-B to A-B, A-B). From these three predictions, Osgood interpolated a full three-dimensional surface depicting how changes in cues, targets, or both should be expected to affect memory performance (Fig 1).

Despite the foundational nature of relatedness for learning and memory, the full space of Osgood's predictions and the conditions under which RI versus RF occurs under various paired associate learning arrangements has remained largely untested. To the extent that prior studies have examined sub-regions of this space, they have relied upon differing methodological approaches, making it challenging to compare findings within a unified framework. Adequately testing these predictions requires a suite of associative learning studies that estimate retroactive and interdependence effects across a wide range of stimuli varying the semantic relatedness of cues, targets, or both. Such a study presents two primary challenges. First, it requires the ability to obtain reliable measures of semantic relatedness for arbitrary pairs of stimuli, which have become increasingly accessible given rapid progress in models of distributional semantics and large-scale datasets collecting associative norms. Second, obtaining adequate coverage over the full relatedness space requires a lot of data: each point in this space must be estimated from measurements of memory performance across multiple participants.

We addressed these challenges across five large experiments ($N=1000$). Subjects were initially given a list of 45 unrelated word pairs (e.g., sick-push), which we will call *base pairs*. Later, during the learning of what we will call *secondary pairs*, we included four within-participant experimental conditions: pairs in the No Δ condition appeared unchanged (sick-push), while other pairs appeared in the Δ Target (sick-shove), Δ Cue (ill-push), or Δ Both (ill-shove) conditions. A final subset of pairs in a control condition remained unshown in this phase (Fig 1A). Subjects were trained until each pair was correctly retrieved once, after which the pair dropped out from later rounds of learning. Condition assignments were counterbalanced, such that the same base pair was rotated across these five secondary pair conditions across every five subjects (Fig 1B). In our initial experiments, we used a stimulus set with a narrow range of

relatedness values, corresponding to the direct associative pair strength. In later experiments, to address how these initial results generalized beyond local semantic neighborhoods of direct associations, we used a stimulus set with a wider range of relatedness that included truly unrelated associations. Additionally, interference often differs depending on the delay between learning interfering material and test (23, 51–55), and we therefore fully crossed the narrower and wider stimulus sets with two different test delays occurring 5-min and 48-hr after secondary pair learning (Fig 1C). Finally, it has been extensively found that engaging in retrieval strongly benefits long-term memory relative to only restudying information (56–58). We therefore conducted a final experiment exploring whether the results changed if subjects only studied during learning (while controlling for overall exposure to the pairs).

Our large sample sizes allowed us to test the memorability of each base pair in each condition across subjects, eliminating incidental effects of the individual base pairs. We measured retroactive effects using each of the following conditions as a difference from the control condition: No Δ at the cue and identity point, Δ Target as a line of values at cue identity spanning target relatedness, Δ Cue as a line of values at target identity spanning cue relatedness, and Δ Both as a surface spanning bivariate cue and target relatedness (see Fig 1D for illustration using the narrower stimulus set and Fig S1 using the wider set). Putting these different conditions together, we show how our paradigm could produce Osgood's proposed surface in Fig 1E, which we test empirically below. Note that if increasing relatedness among word pairs along one or more dimensions increased RI, it would run contrary to Osgood's predictions. Conversely, if increasing relatedness increased RF, it would support his predictions. Such results would also support recursive reminder theory, and a further prediction of this theory is that relatedness would promote interdependence between associated memory traces.

Figure 1: Overview of conditions, stimuli, experiments, variables, and Osgood's predictions. (a) After base pair learning, pairs were divided into five experimental conditions for secondary pair learning. After a 5-min or 48-hr delay, both base and secondary pairs were tested. (b) Word pairs were counterbalanced every five subjects into conditions. (c) Overview of the first four experiments by delay and stimulus set. (d) Coverage of variables across associative strength (AS) values in the stimulus set with a narrower range of semantic relationships. Crosses along the Δ Cue (green) and Δ Target (blue) lines show distributions of cue and target relatedness, respectively. Purple crosses inside the surface (scatterplot) show the distribution of bivariate cue and target relatedness in the Δ Both condition. (e) Experimental data hypothetically conforming to Osgood's (1949) proposed surface. Cue and target relatedness span the y- and x-axes, respectively, while memory change for each condition spans the z-axis, relative to the control condition on the $z = 0$ surface. In (d) and (e), example word pairs from (a) were labeled for illustrative purposes. The x-axes were reversed from normal convention to correspond to Osgood's surface. See also Fig S1 for visualizations using the stimulus set with wider semantic relatedness and Tables S1-2 for all stimuli.

Results

High semantic relatedness produced profound retroactive facilitation, especially at long delays

We began by establishing the pattern of retroactive memory effects across our five main conditions in a regime of high overall semantic relatedness. In our first experiment, we operationalized semantic relatedness in terms of associative strength (AS) (59), the (empirical) probability that a second word is freely generated as a response to a given word, as estimated from a large independent population. We chose words for the secondary pair learning phase that predicted their corresponding base words with AS values that were quasi-evenly spaced from the lowest values (pious→holy, which was only generated with probability 0.03) to the highest (moo→cow, which was only generated with probability 0.96). We also imposed a 48-hr delay before testing. We measured base pair memory performance, or accuracy in providing the correct target word at test, across conditions using a one-way (No Δ , Δ Target, Δ Cue, Δ Both, and control) ANOVA, collapsing across all levels of semantic relatedness. We found that condition significantly affected overall memory [$F(4,796) = 126.2$, $p < 0.001$]. Follow-up t -tests indicated differences across all pairwise conditions, following No $\Delta > \Delta$ Cue $> \Delta$ Target $> \Delta$ Both $>$ control (all adjusted $p < 0.002$), which can be found in the top right of Figure 2. In other words,

related associates generally produced RF, although holding the target constant (i.e. ΔCue) benefitted memory more than holding the cue constant (i.e. ΔTarget). Critically, we also found significant RF in the ΔBoth condition, even though there were no overlapping words between the initial and later-learned pairs.

Figure 2: RF versus RI differed by overall stimulus set relatedness, delay, and word pair condition. The narrower stimulus set (top row) featured only single-step semantic associations between base and secondary cues and targets, whereas the wider stimulus set (bottom row) featured a full range of semantic relationships. All comparisons were significant except those labeled with gray bars and 'ns' ($p > 0.1$) or † ($0.05 < p < 0.1$). Data points from individual subjects were jittered slightly for better visualization. See also Fig S2 for secondary pair memory and Table S3 for numerical results.

One possible explanation for the lack of RI effects is the relatively long (48 hr) delay before the final test. Many forms of interference are known to depend on delay (51–54) (see also (60)) and RI effects in particular typically decrease with delay as the interfering material becomes forgotten (23, 55). We therefore reasoned that we may find RI if we repeated the experiment with a shorter delay of only 5 minutes. In this experiment, we again found a significant difference in performance across condition [$F(4,796) = 37.8, p < 0.001$] (Figure 2, top left) but with no evidence of RI. Pairwise t -tests indicated performance followed No $\Delta > \Delta\text{Cue} > \Delta\text{Target} > \Delta\text{Both} = \text{control}$ (all adjusted $p < 0.014$; “=” indicates $p = 0.27$), consistent with our findings for the longer delay. Together, these two experiments demonstrated that high semantic relatedness between initial and later-learned information produced RF.

Under a wider range of semantic relatedness, condition and delay determined retroactive effects

The prior results showed high RF for nearly all experimental conditions. These results were especially surprising in the Δ Target condition, as RI is ubiquitous in these paradigms, especially after short delays. The primary deviation in our variant was that cue and target associations were strongly related. We therefore considered that these effects arose because even the least-related cue and target associations (e.g., pious→holy) were highly similar in the overall semantic space of words because they were all identified from a local semantic neighborhood: all words used in the secondary phase were produced in a single step of free association from the base word. To test this possibility, we expanded the distribution of relatedness to pairs that spanned the full range of semantic relatedness. To quantify relatedness in this stimulus set, we used the cosine similarity [$\cos(\theta)$] between GloVe vector embeddings. These high-dimensional semantic representations were trained on word-word co-occurrence in large text corpora and strongly align with human similarity judgments (61). We chose GloVe values distributed quasi-evenly from -0.14 to 0.95, which encompassed a wide range of associations from those that would be considered unrelated (e.g., sap→laugh) to those which appear as one-step semantic relationships according to our earlier measure of association strength (e.g., blue→red). Aside from the wider stimulus set, the learning procedure was identical.

We tested these new stimuli under both long and short delay conditions for comparison with our earlier results. In the 48-hr delay experiment, we again found that base pair memory differed strongly across conditions [$F(4,796) = 128.3, p < 0.001$], with pairwise t -tests indicating that $\text{No } \Delta > \Delta\text{Cue} > \Delta\text{Target} > \text{control} = \Delta\text{Both}$ (all adjusted $p < 0.002$; ‘=’ indicates $p = 0.056$), again showing facilitation overall (Fig 2, lower right). In the 5-min delay experiment, however, the results were strikingly different. Base pair memory differed across conditions [$F(4,796) = 59.7, p < 0.001$], but we found evidence of RI in the Δ Target condition, such that $\text{No } \Delta > \Delta\text{Cue} = \text{control} = \Delta\text{Both} > \Delta\text{Target}$ (ΔCue vs. control $p = 0.38$; control vs ΔBoth $p = 0.29$; ΔCue and ΔBoth did differ, $p = 0.04$; all others, $p < 0.001$) (Fig 2, lower left). We therefore successfully replicated the classical RI effects, but only under the conditions of low average relatedness and a short delay. Additionally, the finding that the ΔBoth condition did not significantly differ from control in both experiments suggests that subjects may mentally categorize these pairs as novel pairs (resembling classical C-D pairs) when overall relatedness was low. For results from secondary pair testing in all experiments, please see Fig S2.

Target relatedness produced RF and scaffolded new target learning

Having established condition-level effects of facilitation consistent with Osgood’s predictions (1), we next conducted a more direct test by predicting facilitation as a function of relatedness at the level of word pairs. In the first of these analyses, we focused on word pairs in the Δ Target condition. We subtracted the proportion of subjects successfully recalling each pair in the control condition from the proportion in the Δ Target condition, yielding a measure for each individual word pair that is positive for evidence of RF and negative for evidence of RI. We then performed linear regression analyses between this retroactive measure and the semantic relatedness of the pair, using AS or GloVe values depending on the stimulus set. These analyses allowed us to ask whether word pair memorability was directly correlated with relatedness at the item level.

We found that higher semantic relatedness between targets produced greater facilitation in all experiments (all $p < 0.05$; Fig 3A) except for the narrower stimulus set, 5-min experiment, where we found near-ceiling memory performance ($p = 0.75$). Intriguingly, the results from the 5-min and 48-hr delay experiments with the wider stimulus set further clarified how both delay and semantic relatedness additively determined RI or RF. In the 5-min experiment, we found RI for pairs with very low relatedness, which would be conventionally categorized as “unrelated”, as indicated by the significantly negative y -intercept in the regression (lower left of Fig 3A). As

244 relatedness increased, however, items entered a region that did not differ from the control
245 condition. In the 48-hr experiment, there was no difference from the control condition for pairs
246 with very low relatedness, as indicated by the insignificant y-intercept in the regression, but with
247 increasing relatedness, we found significant RF (lower right of Fig 3A). Additionally, in the
248 experiment using the narrower stimulus set and shorter 5-min delay, the Δ Target condition still
249 produced facilitation compared to the control, suggesting that with high enough overall
250 relatedness, temporary RI effects can fully cross over into RF (upper left of Fig 3A).

251

Figure 3: Target relatedness retroactively benefited memory and created interdependence between base and secondary pairs. (a) Across-subject memorability for each base pair was plotted against the target semantic relatedness, with AS and GloVe values in the top and bottom rows, respectively. Relatedness improved memory in all experiments except in the narrower stimulus set, 5-min delay experiment, where overall memory approached ceiling performance. RI occurred with especially low relatedness in the wider stimulus set, 5-min delay experiment, but this interference disappeared with high relatedness. In the wider stimulus set, 48-hr delay experiment, we found no interference with low relatedness and facilitation with high relatedness. (b) Within each base pair target-secondary pair target duo, we plotted across-subject memory dependence against semantic relatedness in all experiments. Higher correlation values indicate that subjects tended to remember or forget both targets in the duo together. Relatedness increased these correlations in three experiments, excluding the narrower stimulus set, 5-min delay experiment. Thick dotted lines show the 95th percentile threshold of dependence levels against all other pairs. See also Fig S3 for intrusion data from this condition.

The recursive reminders account predicts that when one retrieves an initial pair during new learning, the two become interdependent. It also predicts that reminders should increase with relatedness. Therefore, we next asked whether relatedness promoted interdependence between initial and later-learned pairs. We defined interdependence as the proportion of base pair target-secondary pair target duos that were both correct or both incorrect across subjects. For example, if subjects tended to recall 'peace-razor' during base pair testing and 'peace-shave' during secondary pair testing, or failed to recall both of them, these would be interdependent, whereas if only one of the two memories was recalled as often as both or neither of the words, these would be independent. We then correlated this interdependence measure with semantic relatedness. We found memory dependence increased with higher relatedness ($p < 0.01$), except in the narrower stimulus set, 5-min experiment that previously showed near-ceiling memory performance (Fig 3B). Therefore, target relatedness simultaneously resulted in strengthened base pairs and enhanced interdependence between base and secondary pairs.

We also asked whether target relatedness would increase intrusions, or errors from the secondary pair list into the base pair list. That is, we wanted to contrast two accounts. Under an RI-based account, the targets may merge or compete, leading to confusion about the list contexts (e.g., peace-razorshave). Theoretically, this account could produce some intrusions in addition to RF; indeed, lack of interference in RI studies wherein targets are related has been posited to stem from a "loss of differentiation" between semantically related sources (15), and other studies have found greater intrusion errors with increasing relatedness (16–19). Under the recursive reminders account, highly related new targets would simultaneously strengthen old memories due to reminders of the base pair list and would be scaffolded to the cue as part of the secondary pair list, meaning the list contexts remained interdependent, yet distinguishable (e.g., peace-razor-base list/peace-shave-secondary list). We therefore asked whether relatedness increased across-list intrusions of the new target response into the base pair list by correlating the across-subject intrusion rate with target relatedness. In fact, intrusions significantly decreased in the wider stimulus set, 5-min experiment ($p < 0.001$) and otherwise did not increase with target relatedness in any experiment (all $p > 0.08$; Fig S3), supporting the recursive reminders account.

Cue relatedness had no significant linear effect on base pair memory

Overall, performance in the Δ Cue condition showed consistent RF across experiments. We next asked whether memorability differed as a function of cue relatedness, as it did for target relatedness. We found no significant relationship between cue relatedness and word memorability in the Δ Cue – control condition in any experiment, though there were marginally significant effects in the narrower stimulus set, 5-min delay ($p = 0.085$) and wider stimulus set, 5-min delay experiments ($p = 0.056$) (others, $p > 0.28$; Figure 4). We also repeated the memory dependence analyses between base pair target-secondary pair target duos in the Δ Cue condition. We found inconsistent results: dependence increased with cue relatedness in the narrower stimulus set, 5-min experiment ($p = 0.01$) and the wider stimulus set, 48-hr experiment ($p < 0.001$), but not in the others (both $p > 0.23$; Fig S4). Therefore, even though word pairs in the Δ Cue condition showed RF overall, the relationship between cue relatedness and memorability was non-existent to weak, standing in contrast to those in the Δ Target condition. Memory dependence between base and secondary pairs appeared more statistically reliable, though it was unclear under which conditions dependence between base and secondary pair memories arose.

Figure 4: Cue semantic relatedness has no consistent retroactive effect. Across-subject memorability for each base pair – control was plotted against cue relatedness [top: AS; bottom: GloVe]. Relatedness had no effect on memory in any condition. See also Fig S4 for dependence correlations.

Bivariate cue and target relatedness improved long-term memory and increased memory dependence

Overall, we found that performance in the Δ Both condition showed RF in the narrower stimulus set, 48-hr delay experiment, but it did not differ from the control condition in the other experiments. We next asked whether these retroactive effects differed as bivariate values of cue and target relatedness in all experiments, with particular interest in the narrower stimulus set, 48-hr delay experiment. To do this, we computed base pair memorability in the Δ Both and control conditions for each word pair, and then we computed locally smoothed surfaces based on memorability at each bivariate cue and target relatedness value (see Methods). To assess statistical significance, we first looked for clusters of values whereby the true values exceeded those expected by chance by randomly scrambling the conditions. We then used 1000 permutation tests to assess the size of clusters exceeding this threshold that we might expect due to chance, and we asked whether any observed true clusters exceeded this threshold. We found a significant cluster with high levels of both cue and target relatedness in the narrower stimulus set, 48-hr delay experiment ($p = 0.001$) and not the others (all $p > 0.41$), demonstrating that long-term RF occurs with high bivariate levels of relatedness (Fig 5A). We also computed memory dependence between base pair target-secondary pair target duos in the Δ Both condition, and we similarly created locally smoothed surface plots of these dependence values. Like the memorability analyses, we found a cluster at high levels of both cue and target relatedness only in the narrower stimulus set, 48-hr delay experiment (Fig 5B). Therefore, results from the narrower stimulus set, 48-hr delay experiment concur with findings in the Δ Target condition whereby relatedness simultaneously strengthens base pair memory and increases dependence between base and secondary pair memory. For qualitatively similar results correlating retroactive benefits and memory dependence, except with a linear measure against the added value of cue + target relatedness, see Fig S5.

Figure 5: High cue and target relatedness promoted long-term RF and increased interdependence. (a) We plotted a smoothed surface of $\Delta\text{Both} - \text{ctrl recall}$ values against cue and target relatedness on the x and y axes [top: AS; bottom: GloVe]. Under the narrower stimulus set in the 48-hr delay experiment, memorability increased at high levels of both cue and target relatedness. (b) Similar to (A) except depicting smoothed surfaces of base pair-secondary pair dependence. High values of cue and target relatedness increased dependence in the narrower stimulus set, 48-hr delay experiment. Sections of these plots with purple grid marks were significant, whereas those with white marks were not. See Fig S5 for linear contrasts between cue + target relatedness and memory and dependence measures.

Osgood-style retroactive and dependence surfaces

What happens to an association after its initial formation, and when do two memories become linked? We now attempt to answer these questions by consolidating all experimental conditions in the style of Osgood's surfaces (1). Surfaces from all retroactive memory results can be viewed together in Figure 6, though we will start by examining the narrower stimulus set, 48-hr experiment (right side of Fig 6A and upper right of Video 1). Consider that after base pair learning, the strength of any given association sits along the x-y plane, where target and cue relatedness of a putative secondary pair lie along the x and y axes, respectively. If no related pairs occur during secondary pair learning (control condition), it remains along this axis (orange). If during secondary pair learning, the same pair is learned again (No Δ condition), it sits at the target identity, cue identity point (red). If cues remain and targets change (Δ Target condition), it varies by target relatedness along the cue identity line (blue). If targets remain and cues change (Δ Cue condition), it varies by cue relatedness along the target identity line (green). Finally, if both cues and targets change (Δ Both condition), it rests upon the surface as a bivariate function of cue and target relatedness (purple). Examining results from this experiment, as secondary pair relatedness approaches or reaches full identity along multiple dimensions, memorability improves (though note that the linear relationship along the target identity line is not significant). All conditions from all other experiments are shown on the left of Fig 6A and the other quadrants of Video 1, which shows rotations around the 3-D space.

Figure 6: Osgood-style surfaces depicting retroactive effects and dependence. (a) We plotted all conditions (versus control) from all experiments in three-dimensional coordinates, with cue and target relatedness on the y- and x-axes, respectively, and retroactive memory change on the z-axis, with RF and RI in the positive and negative directions, respectively. (a, right) For the narrower stimulus set, 48-hour delay experiment, we plotted memory for the No Δ - control condition ($\pm$ across-pair standard deviation) at the cue identity, target identity corner point (red circle). We plotted Δ Target - control condition memory along the cue identity line against target relatedness ($\pm$ standard error from the ordinary-least-squares regression fit) (blue), and we plotted Δ Cue - control condition memory along the target identity line against cue relatedness ($\pm$ standard error from the ordinary-least-squares regression fit) (green). We plotted Δ Both - control condition memory as a locally smoothed surface as a bivariate function of cue and target relatedness (purple). Transparent surface grids above and below zero represent $p < 0.01$ significance boundaries from permutation tests, beyond which the surface is significant, as indicated by a darker shade of purple. (left) Similar plots created for all conditions from the other experiments. (b) Dependence for all experiments and conditions formatted similarly to (a).

In addition to considering retroactive base pair effects in isolation, we similarly plotted memory dependence between base and secondary pairs as a function of cue and target relatedness. Examining the narrower stimulus set, 48-hr experiment (right of Fig 6B and upper right of Video 2), dependence increased with relatedness along multiple dimensions, including near the cue identity, target identity portion of the bivariate surface, in a manner resembling the retroactive effects. All conditions from all other experiments are shown on the left of Fig 6B and other quadrants of Video 2; once again, the lack of dependence along the Δ Both surface in the wider stimulus set experiments accords with a likely independence between old and new pairs

under lower average relatedness. Overall, these results strikingly show how semantic relatedness – examined via multiple types of associations – produced retroactive benefits and memory dependence.

When subjects learned by studying, relatedness retroactively benefited memory in the Δ Target condition but did not increase dependence

The prior experiments required one successful retrieval per word pair during learning. Prior research suggests that retrieval produces profound long-term memory benefits relative to a different learning strategy of studying (e.g., (62)) and may also differ in ways relevant to our effects. For instance, subjects may engage in more mental elaboration during retrieval than study, which may help form semantic mediators that can aid in retrieving a memory trace (e.g., retrieving ‘mother-child’ may activate the mediator, ‘father’) (58) and can have benefits for related material (63). Therefore, our final experiment used the narrower stimulus set and a 48-hr delay, but subjects only studied the associations during learning. To control for overall exposure to the pairs, we yoked each of 200 subjects to the exact learning order of subjects in the narrower stimulus set, 48-hr delay experiment. We chose this stimulus set and delay because we were especially interested if the results in the Δ Both experiment from the otherwise equivalent retrieval-to-criterion experiment would generalize to study-only conditions. Condition affected base pair memory [$F(4,796) = 48.9, p < 0.001$], but here t -tests indicated memory followed a Δ Target = No Δ = Δ Cue > Δ Both > control pattern (Δ Target vs. No Δ , $p = 0.94$; Δ Target vs. Δ Cue, $p = 0.25$; No Δ vs. Δ Cue, $p = 0.25$; all others, $p < 0.001$). Therefore, the presence of related associates again aids base pair memory, but in this case, there was very little continued benefit for encountering identical associates while practicing repeated study alone in the No Δ condition (64). In all correlations between retroactive effects and base pair-secondary pair dependence with relatedness, only Δ Target retroactive memory correlated with target relatedness ($p = 0.02$). Correlations in the Δ Cue condition were not significant ($p = 0.85$), nor were any clusters along the Δ Both surface ($p = 1.0$). Intriguingly, correlations between relatedness and memory dependence were not significant in any condition (all $p > 0.24$), suggesting that retrieval during learning may promote more interdependence than study (58). See Fig S6 for all related plots.

Semantic relatedness accelerated new learning

New learning generally benefits from relatedness, whether via associations between words within a pair [e.g., (65)] or with prior learning (17, 30, 36, 66–69). Therefore, we also examined the overall effects of condition and relatedness levels on secondary pair learning in all experiments employing retrieval-to-criterion learning (the study-only experiment had no learning measure). Accordingly, in the narrower stimulus set experiments, the number of trials to criterion followed a No Δ < Δ Cue < Δ Target < Δ Both pattern (Fig S6). The wider stimulus set experiments produced a somewhat similar pattern of No Δ < Δ Target < Δ Both = Δ Cue, where instead Δ Target and Δ Cue flipped from the narrower stimulus set. We next investigated learning across subjects (average trials to criterion per secondary pair) as a function of relatedness in the Δ Cue, Δ Target, and Δ Both conditions. Higher cue relatedness produced faster secondary pair learning in every experiment (all $p < 0.005$). Similarly, higher target relatedness produced faster secondary pair learning in every experiment except the narrower stimulus set, 48-hr experiment ($p = 0.17$; all others $p < 0.05$). Finally, additive cue + target relatedness generally produced faster secondary pair learning in the narrower stimulus set experiments (68) (5-min delay: $p = 0.01$; 48-hr delay: $p < 0.001$), but not in the wider stimulus set experiments (both $p > 0.59$). These results suggest again that secondary pairs in the Δ Both condition in the wider stimulus set are largely treated as new pairs due to the extent of change, as they do not strengthen, nor are they strengthened by, base pairs. Overall, these results suggest that

previously learned base pairs scaffold and speed learning of secondary pairs as a function of their relatedness.

Next, we wanted to rule out an alternative possibility raised by these results. Secondary pairs with high relatedness were learned more efficiently, meaning that they had fewer exposures. If the number of exposures increased RI, this would suggest our RF effects could stem in part from lesser interference. We conducted two analyses to address this possibility. First, we correlated new learning efficiency with memorability across pairs in each condition. We found generally weak evidence in favor of this idea, with significant ($p < 0.05$) results in only the Δ Target condition in the wider stimulus set, 48-hr delay experiment ($r = 0.30$, $p = 0.02$). Full results can be seen in Table S4. Second, we ran partial correlations between relatedness and memorability across pairs while controlling for new learning efficiency. These partial correlations remained significant in all of the main analyses above, including in the Δ Target condition in the narrower stimulus set, 48-hr experiment ($r = 0.34$, $p = 0.026$), wider stimulus set, 5-min delay experiment ($r = 0.45$, $p = 0.002$), and wider stimulus set, 48-hr delay experiment ($r = 0.36$, $p = 0.016$) and for cue+target relatedness in the Δ Both condition in the narrower stimulus set, 48-hr experiment ($r = 0.41$, $p = 0.005$). Full results from these partial correlations can also be seen in Table S4. Therefore, it appears our RF effects did not rely on the amount of pair exposure during secondary pair learning.

Examining retroactive memorability and memory dependence effects with a common metric and with other relatedness metrics

Above, we featured the relatedness dimensions we originally chose to continuously span the stimulus spaces (AS for the narrower stimulus set and GloVe for the wider stimulus set). However, we wanted to address two remaining points. First, the two stimulus sets span variable ranges of relatedness. We kept analyses for these experiments separate because sensitivity to the overall distribution of relatedness within a particular session could affect subject performance; nevertheless, we acknowledge that using different ranges could result in the effects disappearing when the data become combined under a unified metric. To address this concern, we combined across-subject memorability and dependence across stimulus sets in each experimental condition within a particular test delay (e.g., the narrower and wider stimulus sets within the 5-min delay experiments). Next, we correlated these with measures with GloVe values (Fig S8). Notably, none of the prior significant effects disappeared under this analysis. Rather, retroactive and memory dependence effects in the Δ Cue condition actually became significant under this common metric, with increased power, yet they remained weaker than in the Δ Target condition, consistent with our prior results.

The second remaining point is that many other relatedness metrics exist (besides AS and GloVe), which can be broadly categorized into “internal” models relying on relationships within associative semantic networks and “external”, vector-based models based on recently developed algorithms trained on large amounts of text that can measure word-word relationships (70). In some cases, internal models outperform external models at capturing paired associate memory effects (71). Additionally, semantic network relationships can predict paired associate memory beyond single steps to nearby neighbors, with significant benefits shown up to two (3, 72) or three (73) semantic steps. We therefore included the following relatedness factors based on semantic networks: forward AS, or cue $\rightarrow\Delta$ cue and target $\rightarrow\Delta$ target AS rather than the backward (e.g., cue $\leftarrow\Delta$ cue) AS measure used in our analyses above; backward mediator strength, which calculates the cumulative strength of all secondary associations (e.g., mane-tiger via the mediator, lion, or cue $\leftarrow$ [mediator] $\leftarrow\Delta$ cue) and has been shown to predict memory independently from direct AS (65, 72); weighted path length, whereby we find the shortest path in a semantic network generated by free association norms and add up their summed weights between each node; and spreading activation strength, wherein we start from the target word and follow all edges to nearby nodes (words) up to three steps and

add up activation values weighted by their association norms [see (70, 74, 75) for similar approaches]. In addition to GloVe, we also used the following external models: word2vec $\cos(\theta)$, wherein words are represented by vectorized representations based on training a neural network on a large text corpus (76); and latent semantic analysis (LSA) $\cos(\theta)$, which captures contextual similarity between words/documents via projections into a high-dimensional semantic vector space (77). See Tables S5-6 for correlations among these metrics for our stimuli and table S7 for relationships with base pair memory and memory dependence. Although the results differed somewhat by experiment and condition, the backward AS and GloVe measures we used in our analyses above captured the same general effects.

Discussion

We showed that semantic relatedness during learning profoundly benefited memory by retroactively strengthening old associations while scaffolding new ones. We largely found long-term RF across experimental conditions (versus control), which increased linearly with relatedness in the Δ Target and Δ Both conditions. In the stimulus set experiments featuring a wider range of semantic relationships, we found a typical RI effect when relatedness was low and there were short delays after new learning, but both the relatedness of the individual word pairs and the longer delay additively reversed these RI effects into RF. Furthermore, memory dependence (between base and secondary pairs) increased with relatedness in the Δ Target and Δ Both conditions. In the paragraphs that follow, we will argue that these results strongly support theory on recursive reminders, and we next interpret our effects in each learning condition in light of this theory. We follow these interpretations with a possible neurobiological mechanism and a discussion of Osgood's proposal.

Theory on recursive reminders posits that remembering past events during new learning can benefit memory (20, 24, 78–83). The recursive reminders account has three notable aspects here. First, providing explicit reminders or encouraging subjects to recall or integrate past events just before new learning seems to reduce RI (21–23, 84) (and reduce interference in other paradigms (38–41, 85)) or even produce RF (80, 86). Crucially, subjects must both *notice* a change and *recollect* the changed material for these benefits to arise (27, 87, 88). Second, although these reminders can be directed via instructions, they can also occur spontaneously (20, 24, 83, 89, 90). Relatedly, either strong pre-experimental associations or new episodes linking a target and competitor – which could cause subjects to recollect linked information even when uninstructed – can lower (91) or reverse memory impairment effects (63, 92–94). Third, recursive reminders create interdependence between initial and later-learned information that preserves memory for individual temporal contexts. Interdependence – as measured by whether memories are remembered or forgotten together – can develop for pre-existing or newly learned associations and generally aids memory (25, 28, 95–99). Moreover, reminders also scaffold new learning, such that recollecting changes during the formation of new memories aids their retention (27, 79, 86–88, 99).

Broadly, in accord with the recursive reminders account, we propose that strong pre-existing associations between base and secondary pairs produces retroactive benefits by increasing the likelihood of subjects recollecting base pairs and relating them to secondary pairs, thereby increasing both base pair memory and dependence. Critically, the absence of greater intrusions with higher relatedness suggests that temporal order information regarding the learning list of each pair was preserved rather than the two contexts becoming confused. That is, with high relatedness, recursive reminder-induced memory benefits outweighed the possible countervailing force of competition at retrieval. With weaker pre-existing associations, we speculate that subjects noticed changes while learning new secondary pairs but may have been less likely to recall and integrate them with corresponding base pairs.

We now discuss our results and how they support the recursive reminders account in each condition. The Δ Target condition showed clear retroactive effects except in the presence

of ceiling performance: (1) target relatedness linearly increased RF, including when subjects only studied the information; (2) RI/RF depended on the delay, such that, under the wider stimulus set experiments, RI occurred with a short delay, whereas higher relatedness rescued individual pairs from RI to no effect, and with a longer delay, relatedness increased benefits from no effect to RF; and (3) base pair target-secondary pair target duo dependence increased with target relatedness (except this also did not occur in the study-only experiment). As introduced above, these effects likely stem from two competing processes: a temporary retrieval impairment due to high competition with the more recently learned target word, and a long-term strengthening and interdependence effect that increases linearly with relatedness. High relatedness between base and secondary pairs means that during secondary pair learning, base pairs are reactivated via recursive reminders and secondary pairs become scaffolded to them. These results mirror other phenomena that differentially affect short-term and long-term memory performance, such as the testing effect (62, 100). Although we have largely avoided comparing 5-min and 48-hr delay results directly because they were part of different experiments, it appears visually that conditions in which we expect recursive reminders tend to slow the rate of forgetting (relative to the amount of forgetting in the control condition). This pattern suggests recursive reminders act as effective retrieval processes, similar to the testing effect (20).

In contrast to the Δ Target condition, RF tended to occur overall in the Δ Cue condition, with null effects in the re-study experiment and the wider stimulus set, 5-min experiment, and featured a weaker relationship with cue relatedness. It is less clear whether and how effectively recursive reminders occur in this condition. In one sense, the absence of a relationship between relatedness and memorability (or the presence of a very weak benefit that remained insignificant in our main analyses) could suggest less recursive reminding and that most benefits occur due to a combination of increased availability of target responses (in the absence of competition at retrieval). Indeed, increasing response availability has been proposed to occur independent of associations (101), and rehearsing B responses alone can improve A-B memory (102). However, weak relatedness benefits in this condition across all experiments indicate that subjects may perform a mental ' Δ cue $\rightarrow$ cue $\rightarrow$ target' operation during secondary pair learning that would require recollecting the original association as a recursive reminder. Altogether, the retroactive benefits are clear in the Δ Cue condition, but the mechanism seems to differ from the Δ Target condition and the extent to which recursive reminders are specifically involved versus other processes such as increased target availability is unclear.

Strikingly, in the Δ Both condition, RF occurred overall (versus control) and at high values of cue and target relatedness in the narrower stimulus set, 48-hr delay experiment. Moreover, base pair-secondary pair dependence similarly occurred at high cue and target relatedness in this experiment. These results suggest that, as in the Δ Target condition, there was an increased likelihood of recursive reminders supported by pre-existing associations. These effects occurred when cue and target relatedness were high, possibly because changing both causes subjects to fail to recollect both pre-existing links and/or attribute the secondary pair to a new memory (103). Additionally, null effects in the wider stimulus set experiments – even for pairs with high cue and target relatedness – suggest that relatedness across pairs may also need to be high on average for subjects to start noticing and recollecting changes rather than attributing the pairs to entirely new associations.

Overall, we propose that relatedness increases the likelihood of recursive reminders, which create well-fortified and interdependent sets of associations that maintain and even strengthen memories while preserving information such as their temporal and contextual order (20, 26, 27). These explanations rely heavily on the importance of interdependencies among base and secondary pairs, a concept elucidated by paradigms featuring multi-element “closed-loop” learning configurations (95–97) like A-B, B-C, and A-C. These configurations enhance memory and the interdependence between associated elements more than similar, “open-loop”

configurations like A-B, B-C, and C-D. In this framework, our high relatedness Δ Target and Δ Both conditions resemble a closed loop, except that rather than having to learn the final link in the loop *de novo*, unrelated associations are closed by the pre-existing target relationship in the Δ Target condition and by both pre-existing cue and target relationships in the Δ Both condition. These results demonstrate a clear interplay between semantic and episodic representations, whereby semantic representations scaffold the formation and retention of episodic memories (8, 104). Finally, under Δ Target learning, testing causes subjects to recollect stimulus changes more often than restudying (88). Therefore, in our study-only experiment, interdependencies may not have emerged because subjects were not forced to incorporate changes occurring between base and secondary pairs into an integrated memory trace, suggesting that testing during learning is critical for forming these interdependencies (58).

Neural results also support the idea that retrieving earlier memories during new learning aids memory and interdependence. Generally, the neocortex supports networks of semantic information, whereas the hippocampus binds together elements specific to episodes (96, 105). Retrieval cues often elicit reactivation of incidental (non-target) information in hippocampus (106) or neocortex (60, 96) [which in turn coincides with greater hippocampal activity (96)]. Reactivation in cortex (21, 107) or hippocampus (108) during new learning predicts resistance to interference and inference for information linked by a common element (e.g., A-C after A-B and B-C learning) (109, 110). Moreover, instructions to integrate cause subjects to form neural patterns distinct from ordinary encoding, which predict behavioral measures of integration (21, 111). These results all suggest that recollection during new learning reactivates and strengthens old memory traces, promoting resistance to interference and interdependence. Finally, evidence from rodents suggests that neurons encoding prior memories are reactivated upon learning related experiences (112, 113), offering a plausible way in which integration can occur. Furthermore, blocking hippocampal plasticity during new, overlapping events prevents transfer between the two memories, suggesting a *causal* role for the hippocampus in this process (114).

Given these findings, we now speculate on how our effects fit within a neurobiological framework extending the recursive reminders account (Fig 7). In our study, pre-existing semantic relationships existed primarily within the neocortex, while previously unrelated pairs were bound by the hippocampus along with their episodic list context and novel, related episodes could also have been interdependently linked within the hippocampus. The No Δ condition generally produced maximum strengthening for both base and secondary pairs. In line with a theory suggesting that even repetitions of the same learning material creates multiple traces within the hippocampus (115), these context memories were formed individually yet, as shown by their strong interdependence (red, leftmost point in Fig 6B), they were strongly bound within the hippocampus. In the Δ Target and Δ Both conditions (and to a lesser extent in the Δ Cue condition), high relatedness between base and secondary pairs – represented by pre-existing cortical links – facilitated base pair reactivation via recursive reminders, thus creating an inter-hippocampal association and behavioral dependence. Such benefits were far more limited with no or low relatedness. Additionally, though we propose that these interdependencies initially rely on the hippocampus, the novel associations may eventually become linked within the cortex with more repetitions (57, 105). Altogether, the model in Fig 7 provides a simplified, speculative explanation for our collected results and a testable mechanism for future studies.

Figure 7: Proposed neurobiological schematic of long-term memory fates across conditions and two levels of semantic relatedness. Initially, unrelated base pair associations are bound in the hippocampus along with base list (BL) contexts (e.g., “plaza-doze-base list” and “beer-late-base list”; left column), followed by new associations in secondary list (SL) contexts. Subjects can thereby retrieve target words given a cue and list context. Cortical associations are absent for words without pre-experimental relatedness (top) and strong for words with high pre-experimental relatedness (bottom). Relearning A-B (No Δ condition; second from left column) under either level of relatedness results in strengthened base pair and robust secondary pair associations (e.g., “plaza-doze-secondary list”), likely as linked episodes within the hippocampus. The consequences for learning a pair with a new target (Δ Target condition; middle column) differs based on pre-experimental relatedness: with no relatedness (top), little to no long-term change occurs to the base pairs and secondary pairs are independently formed (e.g., “plaza-plus-secondary list”), whereas with high relatedness (bottom), the original memory is strengthened as the new memory is formed (“keg-late-secondary list”). Moreover, the episodes become bound within the hippocampus, forming an interdependent memory trace. Note that RI effects shown in the narrower stimulus set, 5-min delay experiment are not represented by this long-term schematic and likely stem from more temporary retrieval impairments. Learning a pair with a new cue (Δ Cue condition; second column from right) generally strengthens the original memory (perhaps due to better target accessibility) in a manner only weakly reliant on cue relatedness. The consequences for learning a pair with two new words (Δ Both condition; rightmost column) differ markedly based on pre-experimental relatedness: with no relatedness (top), the new association memory is formed independently, whereas with high relatedness (bottom), the base pair memory becomes strengthened, and the base and secondary pair associations become interdependent.

How do our results support or refute the key ideas in Osgood’s (1) proposal? The presence of retroactive benefits that increase along the cue identity line strongly support his proposal that RI becomes RF with high target relatedness. However, note that we only found the full crossover from RI to RF across experiments – such as across delays by contrasting both wider stimulus set experiments or across overall levels of relatedness by contrasting the narrower and wider 5-min experiments – rather than finding the crossover within the same experiment. RF (and the total absence of RI) along the target identity line supports his proposal, but conversely, the absent (or very weak) positive relationship with cue relatedness in all experiments does not. Finally, along the bivariate surface, we found benefits when the relatedness among both dimensions was very high, but no reliable effects otherwise; such an effect is present visually on Osgood’s proposed surface, but it had lacked empirical support. We also assert that there is no *one* surface, as we produced surfaces that varied both by overall relatedness and delay. Note that we explored a wide range of semantic relatedness in later experiments, but one could consider even further notions of relatedness. When later-learned information differs in even more substantial ways, such as when numbers, letters, or famous people are presented when trying to recall one of the other categories, RI tends to decrease again because the different categories reduce competition during retrieval (12). Therefore, if one took the wider stimulus set, 5-min delay surface and expanded stimulus relatedness into domains beyond words, RI may decrease again, producing a non-linear effect reminiscent of

those found across early studies employing a wide variety of stimulus types, including with numbers, number-letter combinations, nonsense syllables, abstract visual symbols, poetry, and prose (116–125). Additionally, future studies could explore how surfaces differ based on less nameable stimuli types, such as stimulus spaces with continuous, quantifiable changes in visual stimuli (e.g., (126–129)), or other domains (130).

A notable limitation of our study is that we did not dissociate between semantic representations based on distributed representational models [e.g., (61, 131)] and associative relations based on association strength and spreading activation [e.g., (132)], instead relying on the broad term, semantic relatedness, to capture both constructs. Analyses in Table S6 did not indicate any clear distinction in correlations with memorability and interdependence between measures of semantic and contextual similarity such as LSA and word2vec versus associative strength. Nevertheless, we did not aim to directly contrast these two constructs by selecting stimuli that dissociate them, and given that the two types of relations show different effects on cognition [e.g., (133)], this will be important in future work.

We began this investigation by asking two fundamental questions about learning: when does a new memory facilitate versus interfere with an older one, and when do their fates become linked? Inspired by a never-fully-tested, seven-decade-old proposal (1), we produced a consolidated account suggesting that semantic relatedness between old and new memories facilitates old memory strength and promotes their interdependence. When a new memory bears high relatedness to an old one, subjects can readily notice the change and recollect the old memory, fortifying the old memory and scaffolding the new one to it, providing mutual reinforcement (134). To return to our opening example, if after learning about sweet vermouth, the bartender notices and recollects the change when learning about dry vermouth, the sweet vermouth memory becomes strengthened, and the vermouth memories become linked. Ultimately, these findings highlight and strongly reinforce the importance of building on prior knowledge in educational (135) and aging (136) domains and clarify when and how complex networks of knowledge can be accumulated and retained.

Methods

Subjects. For each experiment, we chose a sample size of 200 – large relative to most memory studies – to ensure that memorability measures from each condition would have reliable data given the 5-fold counterbalance (200 subjects / 5 counterbalances = 40 measurements for each independent word pair contrast). All subjects across the five experiments were undergraduate students with normal or corrected-to-normal vision who received psychology course credit for participating. In each experiment, subjects with overall memory performance less than 4 standard deviations below the mean were excluded and subjects were run until 200 remained. In the study-only experiment, we additionally dropped subjects with no correct responses in the base pair condition, even though it was within 4 standard deviations of the mean. Additionally, numerous subjects did not return or complete the final test. The final breakdowns were as follows: narrower stimulus set, 5-min delay: N = 201, 0 no test, 136 females (135 post-exclusions); narrower stimulus set, 48-hr delay: N = 208, 6 no test, 114 females (108 post-exclusions); wider stimulus set, 5-min delay: N = 206, 0 no test, 101 females (99 post-exclusions); wider stimulus set, 48-hr delay: N = 212, 7 no test, 149 females (139 post-exclusions); study-only: N = 226, 6 no test, 177 females (156 post-exclusions). In the original (retrieval-to-criterion) narrower stimulus set, 48-hr experiment, subjects took the experiment on lab computers. Later experiments were conducted online due to the COVID-19 pandemic. Timing in the online experiments was identical, and subjects took the experiment while in virtual sessions with research assistants to enhance attentiveness to the task. All subjects were recruited via an online scheduling software. Subjects provided informed consent, and all procedures were in accordance with the California Polytechnic State University, San Luis Obispo Institutional Review Board.

Stimuli. Since there are numerous word attributes (e.g., word frequency) by which verbal memorability differs (137–141), we designed our experiments so that the main measure of interest (base pair memory) used the same 45 word pairs, with the only manipulations being the condition of secondary pair learning and the semantic relatedness between base and secondary pairs.

Stimuli selection proceeded in two stages: first, we found paired words of varying relatedness that would later become a cue- Δ cue unit or target- Δ target unit, and second, we created pairs of pairs (comprising a cue, Δ cue, target, and Δ target word). In the first step in the stimulus set with a narrower range of semantic relationships, we aligned 3-5 letter words by free AS from an open database (59) and selected 90 unique pairs ranging approximately evenly from 0.03 (pious→holy) to 0.96 (moo→cow). Note that AS relationships are directed and can affect cued recall memory (31, 142), so we controlled for these asymmetries by always designing the cue word from the database (e.g., moo) to the secondary pair (Δ cue or Δ target) and the target word (e.g., cow) to the base pair (cue or target). Our logic was that secondary pair learning would thereby retroactively “act upon” base pair learning in a predictable way (based on the AS value) rather than vice versa. In the first step in the stimulus set with a full range of semantic relationships, we derived pairwise Global Vector (GloVe) cosine similarity [$\cos(\theta)$] values (61) for all 3-5 letter words from the same free association database. The GloVe training set involved 840 billion web tokens and were imported using the gensim Python toolbox (<https://github.com/RaRe-Technologies/gensim>) (143). We then chose words to quasi-evenly span the full interval of $\cos(\theta)$ values ranging from -0.14 to 0.95. These relationships are undirected and therefore the base versus secondary pair decisions were somewhat arbitrary but remained consistent for all subjects after initial determination.

Within each experiment, we aimed for each subject to experience similar overall levels of semantic relatedness across pairs. Therefore, in the second step of creating the stimuli, we separated all 90 chosen pairs into thirds by semantic relatedness (30 pairs each) and randomly assigned 30 pairs from each split into 15 cue pairs (cue and Δ cue) and 15 target pairs (target

and Δ target). Then we randomly assigned the 15 cue pairs from each relatedness level to one of three target pair levels and vice versa, meaning that all pairs were essentially assigned to ninths of a 2-D grid (with 5 cue and 5 target pairs in each ninth). Effectively, these ninths could be classified by low-moderate-high (l/m/h) semantic similarity for cues and targets, respectively, as l/l, l/m, l/h, m/l, m/m, m/h, h/l, h/m, and h/h. Next, we randomly paired the pairs within each ninth so that each had 5 pairs of pairs consisting of cue, Δ cue, target, and Δ target words that could be assigned to any experimental condition. Our counterbalance separated one item from each ninth into each of the five experimental conditions and therefore multiples of five subjects were required to maintain counterbalances across stimuli.

Other relatedness metrics.

Forward (cue $\rightarrow\Delta$ cue and target $\rightarrow\Delta$ target) AS and backward mediator strength values (e.g., cue $\leftarrow$ [other word] $\leftarrow\Delta$ cue) were taken from the same repository (59) from which we found cue $\leftarrow\Delta$ cue and target $\leftarrow\Delta$ target AS values used in the main analyses. Weighted path length was determined by first finding the shortest path in a network composed of all words within the repository from target to cue word and then adding up the weights. For example, if the Δ cue word was 'stripe' and cue word, 'king', the shortest path may be 'stripe $\rightarrow$ tiger (0.034 AS) $\rightarrow$ lion (0.308 AS) $\rightarrow$ king (0.021). Each weight was computed as $1 - \text{AS}$, so the previous example would have a weighted path length of $[(1 - 0.034) + (1 - 0.308) + (1 - 0.021)] = 2.637$. Note that with all single-step associations in the narrower stimulus set, weighted path lengths were all simply $1 - \text{AS}$. Despite the vast size of semantic networks, they possess small-world architecture with generally small path lengths (144), and indeed all but 6 pairs had lengths of less than 6. These remaining path lengths had infinite length according to our algorithm and were set to 6. For the spreading activation analysis, we performed the following, starting with the target node: (1) at each node, find all edges (to nearby words in free association space) and norm all AS to 1, (2) find activation (if any) of the cue word and log it by its weight, (3) advance along all edges iteratively, and (4) repeat up to three steps, logging as weights the multiplied values of each edge *en route* to the cue word. Then we added up the total activation of the cue across these three steps. For word2vec (76), we used a version of the model trained on Google News with 3 million 300-dimension word vectors. We imported the vectors and calculated similarity using the gensim Python toolbox (143). For latent semantic analysis, we found pairwise cosine similarity values via <http://lsa.colorado.edu> using term-to-term comparisons trained on general reading lists up to the college level with 300 orthogonal factors (77).

Procedure. All experiments followed this order: base pair learning, secondary pair learning, a 5-min or 48-hr delay, base pair testing, and secondary pair testing (Figure 1A). For base pair learning, subjects first viewed the 45 pairs in a round of encoding followed by retrieval to criterion or, in the case of the study-only experiment, repeated study. During encoding, subjects attended to a fixation cross for one second before pairs appeared for four seconds. Cue and target words were shown just above and below the vertical center of the screen, respectively, and both were centered horizontally. During retrieval in the main retrieval-to-criterion experiments, subjects attended to a fixation cross for one second before the cue word was shown. After one second, a blank prompt was shown where subjects could type in their answer. Subjects were given unlimited time to respond, after which both cue and target words were shown as feedback whether correct or not. Correct pairs were dropped from this phase so that the only remaining trials on successive rounds were previously incorrect responses. In the study-only experiment, subjects were given four seconds to re-study the words rather than testing.

Before secondary pair learning, we told subjects they would next learn a new list of pairs and that the stimuli may or may not change between lists. Secondary pair learning then

proceeded with the same retrieval criterion and timing as base pair learning, except that only 36 pairs were learned (corresponding to pairs in the No Δ , Δ Target, Δ Cue, and Δ Both conditions). In the study-only experiment, the yoking procedure for each subject was matched to the learning order of a subject from the retrieval-to-criterion, narrower stimulus set, 48-hr delay experiment. For example, subject #1 from the retrieval-to-criterion experiment was matched with subject #1 from the study-only experiment. We copied the learning order precisely in both base and secondary pair learning phases from each retrieval-to-criterion subject to the study-only subject, so if subject #1 in the former saw 'sick-push' first, so did subject #1 in the latter experiment, and so on. In later rounds of learning, when many word pairs had dropped out for a subject in the retrieval-to-criterion experiment, those same items dropped out for the yoked subject in the study-only experiment. We acknowledge that this procedure cannot control for individual differences in memorability; for instance, subject #1 in the retrieval-to-criterion experiment and subject #1 in the study-only experiment could require different exposures to achieve the same criterion, so the pairs remaining at the end of each learning phase may not be the ones the study-only subject would have struggled to learn. Such differences cannot be addressed without an additional test assessment in the study-only experiment, but we believe that matching the objective amount of exposure serves as a sufficient control for our purposes.

After returning for the test, subjects were first asked to recall all words from the base list (which we described as the 1st list they learned). During the test, subjects attended to a fixation cross for one second before the cue word was shown. They were allowed unlimited typing time and were given no feedback after submitting their response. Following one test of each pair, they were then asked to recall all words from the secondary list (which we described as the 2nd list they learned), which followed an identical format. Subjects were then debriefed and allowed to leave.

Statistics. Across-condition comparisons within each experiment were conducted using one-way (condition: No Δ , Δ Target, Δ Cue, Δ Both, control), repeated-measures ANOVAs. Significant ANOVAs were followed with pairwise, FDR-corrected (145), within-subject *t*-tests.

Across-base pair memorability analyses were conducted first by finding the proportion of subjects who recalled each base pair in each condition. For instance, if subjects #2, 7, 12, and 17 had "copy-angel" in the Δ Target condition and 3/4 recalled it, while subjects #5, 10, 15, and 20 had "copy-angel" in the control condition and 2/4 recalled it, the Δ Target – control memorability for that pair would be 0.25. Next, we ran ordinary least squares (OLS) linear regression analyses between the memorability of that pair and its specific AS or GloVe cos(θ) value. For the Δ Both condition, we added cue + target relatedness values before conducting the regression. In some cases, the y-intercept of the OLS line may be theoretically meaningful (e.g., 0 AS means 0 subjects might endorse a word in a free association task). In all cases, the slope was of interest, indicating whether and how relatedness affected condition-based memorability. Significance for both slope and intercept results were reported in each plot based on *p* values from 'fitlm' in MATLAB, and best-fit lines were plotted with the confidence error output from 'polypredci' in MATLAB (146).

Memory dependence was calculated by first examining memory for each base pair target-secondary pair target duo within a condition across subjects. Consider the following example in the Δ Target condition, where 1 = correct and 0 = incorrect memory and values are represented respectively across subjects. If answers for subjects #2, 7, 12, and 17 when given "peace" as the cue during the base pair test (correct answer: "razor") were 1,1,1,0 and their answers when given "peace" as the cue during the secondary pair test (correct answer: "shave") were 1,1,0,0, the across-subject dependence would be 0.75. Conversely, if the base pair test across the same subjects for the same pair was 1,1,1,0 and the secondary test was 0,1,0,1, the across-subject correlation would be 0.25. It is important to note that, between the extremes of

ceiling and floor performance, dependence and performance are dissociable. A target duo could potentially have a higher rate of dependence than raw memory performance if it regularly became forgotten together. Conversely, a target duo could have a lower rate of dependence than memory performance if one of the two pairs are regularly recalled and the other not. Following this calculation, we performed similar regression analyses with these values plotted against semantic relatedness in each experiment. Additionally, we determined thresholds for each word pair by finding the dependence of each cue-target pair versus all other mismatched, cue- Δ target pairs. Since there were 44 other pairs, our upper threshold was whether the true pair was higher than $43/44 = 0.977$ of the other pairs, which corresponds to a significance threshold of $\alpha = 0.046$. We plotted the average of these thresholds within each experiment as a dotted line on each dependence graph.

To create the memorability surfaces in the Δ Both condition, we first examined the Δ Both – control condition memorability across subjects for each base pair (as above). Next, we found the bivariate cue and target relatedness for each base pair. From this, each pair had three coordinates: a cue relatedness value (which would become the y-coordinate on the surface), a target relatedness value (the x-coordinate), and a Δ Both – control memorability value (the z-coordinate). To obtain a smoothed surface from these data, we used robust spline smoothing of the z values over the x-y surface with a smoothing factor of approximately 40% of the input space (e.g., 0.37 for data spanning 0.93 of AS values and 0.43 for 1.09 of cosine similarity values) (using the ‘smoothn’ function in MATLAB) (147). This smoothing factor was used to cover inevitable gaps in the surface space (see Figure 1D for illustration of this point). Above- and below-zero thresholds in the surface space were calculated like the above using bootstrapped permutation tests, and we similarly smoothed over these surfaces using the same smoothing factor. To assess significance, we found the sizes of 2-D clusters where the true values exceeded the above-zero thresholds. Because a noisy signal could exceed this threshold simply by chance, we next computed the likelihood of finding a cluster of the observed size. To do this, we used 1000 permutation tests, whereby we randomly scrambled whether an across-subject memorability value fell in the Δ Both or control condition, and we found the size of each of these clusters exceeding the above-zero permutation threshold. Finally, we obtained a p value by examining the proportion of permutation tests that our observed cluster exceeded.

Acknowledgements: We would like to thank Anna Leshinskaya and Charan Ranganath for helpful discussions about the project and Xiaonan Liu and Sebastian Michelmann for comments on early drafts of the manuscript. We would also like to thank several R.A.s who helped to run the study, including Lauren Hansen, Lily Sanz, Jacob Van Dam, Kenia Alba, Annika Asp, Kaeley Benedict, Kirrin Bereznak, Nicole Brault, Kylie Capella, Rasha Demeter, Noa Dunevich, Chloe Fleischer, Lauren Garabedian, Samantha Garrett, Shana Gitterman, Olivia Gott, Trevor Guerra, Mackenzie Harrison, Ethan Heh, Erika Holloway, Caitlin Johansen, Jarett Massey, Katherine Miller, Rachel Nebel, Sahar Oliaei, Catherine Palmer, Madeline Phillips, Natalie Phillips, Matthew Reed, Pilar Reyes, Sofía Sanz Galan, Isabella Strawn, Arushi Tewari, Natalie Thomas, Alyssa Tierney, Sarah Tung, and Emma Whitwam.

Declaration of interests: The authors declare no competing financial interests.

Supporting information figures and tables

Figure S1: Wider stimulus set examples and coverage. (a) Sample stimuli from the wider stimulus set in all conditions. (b) Variable coverage. Points along the target identity (green) and cue identity (blue) lines show distributions of cue and target GloVe values, respectively. Purple points inside the surface (scatterplot) show the distribution of bivariate GloVe values in the Δ Both condition. Related to Fig 1A and 1D.

Figure S2: Secondary pair memory changes depending on overall stimulus set relatedness, delay, and word pair condition. All comparisons were significant except those labeled with gray bars and 'ns' ($p > 0.1$) or † ($0.05 < p < 0.1$). Data points from individual subjects were jittered slightly for better visualization. Related to Figure 2.

1175
1176
1177

Figure S3: Intrusions did not increase with target relatedness in the Δ Target condition. (a) Across-subject intrusion rates of secondary pairs into each base pair were plotted against target relatedness [Top: AS; bottom: GloVe]. We found no positive relationships between intrusions and target relatedness, with the wider stimulus set, 5-min delay experiment featuring a significantly negative relationship. Related to Figure 3.

1178
1179
1180

Figure S4: Cue relatedness showed a mixed relationship with memory dependence in the Δ Cue condition. Within each base pair target-secondary pair target duo, we plotted across-subject memory dependence against relatedness in all experiments. Relatedness increased these correlations in the narrower stimulus set, 5-min delay and the wider stimulus set, 48-hr delay experiments. Thick dotted lines depict the 95th percentile threshold of dependence levels against all other pairs. Related to Figure 4.

1181
1182
1183

Figure S5: High cue + target relatedness promotes long-term RF and increases interdependence. (a) We plotted across-subject memorability for each base pair – control against the added cue + target relatedness [top: AS; bottom: GloVe]. Under the narrower stimulus set in the 48-hr delay experiment, memorability increased with relatedness. (b) We plotted across-subject dependence for each base pair target-secondary pair target duo against added relatedness in all experiments. Relatedness increased dependence in the narrower stimulus set, 48-hr delay experiment. Thick dotted lines show the average 95th percentile threshold of dependence levels against all other pairs. Related to Fig 5.

48-hr test delay, study-only experiment

Figure S6: Study-only learning led to semantic relatedness benefits in the Δ Target condition but no base pair-secondary pair dependence. (a) Overall memory performance for base (left) and secondary pairs (right) by condition. All comparisons were significant except those labeled with gray bars and 'ns' ($p > 0.1$) or † ($0.05 < p < 0.1$). Data points from individual subjects were jittered slightly for better visualization. (b) Correlations between retroactive memory effects (left) and base pair-secondary pair dependence (right) in the Δ Target (top), and Δ Cue (middle) conditions. Retroactive memory effects correlated with target relatedness in the Δ Target condition, but no other comparisons were significant. Pearson correlations are shown in the plots followed by * when $p < 0.05$ and ** when $p < 0.01$. On bottom, we plotted retroactive (left) and dependence surfaces (right) in the Δ Both condition. (c) Osgood (1949)-style surfaces for retroactive memory (top) and dependence (bottom) formatted identically to Fig 6. Related to Figs 2-6 and the Results section.

1185

1186

1187

Figure S7: Secondary pair learning differed by stimulus set and condition and generally benefitted from semantic relatedness. (a) Learning time (mean trials to criterion) followed this pattern for the narrower stimulus set: No $\Delta < \Delta$ Cue $< \Delta$ Target $< \Delta$ Both. In the wider stimulus set, learning times for the Δ Cue and Δ Target conditions flipped, following a pattern of No $\Delta < \Delta$ Target $< \Delta$ Both = Δ Cue. All comparisons were significant except those labeled with gray bars and 'ns' ($p > 0.1$) or † ($0.05 < p < 0.1$). Data points from individual subjects were jittered slightly for better visualization. (b) In the Δ Cue condition, average learning time across subjects for each word pair decreased with increasing cue relatedness [top: AS; bottom: GloVe]. (c) In the Δ Target condition, learning time generally decreased with increasing B/B' relatedness [top: AS; bottom: GloVe]. One exception occurred for the narrower stimulus set, 48-hr delay experiment. (d) In the Δ Both condition, learning time decreased with cue + target relatedness in the narrower stimulus set, but not in the wider stimulus set. In (b-d), Pearson correlations are shown in the plots followed by * when $p < 0.05$ and ** when $p < 0.01$. Related to Results section.

1188

1189

1190

Figure S8: Semantic relatedness benefits memory and dependence when combining datasets under a common GloVe metric. (a) We plotted across-subject memorability (top) and dependence (bottom) for the Δ Target (left), Δ Cue (middle), and Δ Both (right) conditions after combining the narrower and wider stimulus set, 5-min delay experiments. For the Δ Both condition, we used added cue + target relatedness. We found significant relationships between relatedness and both memorability and dependence in the Δ Target and Δ Cue conditions. Circles and crosses depict narrower and wider stimulus set data, respectively. Correlations between the combined correlation are plotted in dark colors, with each individual correlation between stimulus set and relatedness replotted in light colors for visual comparison. Text labels reflect correlation values for the combined datasets. (b) We created identical plots except combining the experiments with 48-hr delays. Here all relatedness correlations were significant. Related to Figs 3-4, Fig S5, and the Results section.

Table S1: Cue- Δ cue and target- Δ target pairs and their relatedness factors for the narrower stimulus set. AS: associative strength; MS: mediator strength; Spath: weighted shortest path; SpAct: spreading activation strength; GloVe: global vector $\cos(\theta)$; w2v: word2vec $\cos(\theta)$; LSA: latent semantic analysis $\cos(\theta)$. Bold: relatedness factor of interest. Related to Fig 1.

Table S4: Correlations between base pair memorability and secondary pair learning efficiency (top) and partial correlations between base pair memorability and semantic relatedness controlling for secondary pair efficiency (bottom). For partial correlations, we used backward AS for the narrower stimulus set and GloVe for the wider stimulus set. Bold: significant relationships ($p < 0.05$).

Table S5: Correlations among the relatedness factors for the narrower stimulus set after concatenating cue- Δ cue and target- Δ target lists together. AS: associative strength; MS: mediator strength; Spath: weighted shortest path; SpAct: spreading activation strength; GloVe: global vector $\cos(\theta)$; w2v: word2vec $\cos(\theta)$; LSA: latent semantic analysis $\cos(\theta)$. Bold: significant relationships ($p < 0.05$). These values are specific to this dataset and will vary across datasets or for a full dictionary. Note that the perfect correlation between AS and Spath reflects the fact that Spath is simply $(1 - \leftarrow AS)$ with all one-step associations. Related to Results section.

Table S7: Correlations between various relatedness factors and base pair memorability (top) and base-secondary pair memory dependence (bottom). For the ΔBoth condition, we used the added cue + target relatedness featured in Fig S5. Relationships within each column align with the corresponding measures for that condition (e.g., ← AS indicates target←Δtarget AS in the ΔTarget condition). AS: associative strength; MS: mediator strength; Spath: weighted shortest path; SpAct: spreading activation strength; GloVe: global vector cos(θ); w2v: word2vec cos(θ); LSA: latent semantic analysis cos(θ). Bold: significant relationships ($p < 0.05$). Related to Results section.
