Abstract

Humans care for the wellbeing of some animals (e.g., dogs), yet tacitly endorse the maltreatment of others (e.g., pigs). What treatment is deemed morally appropriate for an animal can depend on whether the animal is characterised as “food”. When such categorisation of animals emerges, and when a moral hierarchy of beings depending on their species-membership (speciesism) develops is poorly understood. We investigate this development across samples of children (9-11-years-old), young adults (18-21-years-old), and adults (29-59-years-old; total $N=479$). Compared to young adults and adults, children a) show less speciesism, b) are less likely to categorize farm animals as food than pets, c) think farm animals ought to be treated better, and d) deem eating meat and animal products to be less morally acceptable. These findings imply that there are key age-related differences in our moral view of animal worth that point to socially constructed development over the lifespan.

Keywords: human-animal relations, meat consumption, morality, speciesism

The development of speciesism: Age-related differences in the moral view of animals

A fascinating aspect of the human mind is the ability for “moral acrobatics” (Rochat, 2021): people regularly hold ethical values that contradict each other and employ moral double standards. Humans divide the world into “us” and “them” and find different treatment of our own and other groups morally acceptable. For example, several countries have legal procedures in place for fair trials of national citizens, while simultaneously detaining immigrants without a trial or timeline for release (Croucher, 2019). One of the areas where moral acrobatics become most apparent is the human species’ relationship to non-human animals. Pet animals are treated with similar care and affection as human friends, and spending time with pets can feel more enjoyable than time with other humans (Lades et al., 2020). Furthermore, many people contribute to animal welfare charities and express concern for dangers to wild animals. Yet, many people also accept great harm to some animals. For example, people readily justify cruel treatment that often happens in factory farming (Piazza et al., 2015). Hence, people care strongly for some animal species and (at least tacitly) simultaneously endorse the maltreatment of others.

Individuals struggle with whether it is morally permissible to eat meat, and whole societies struggle with which legal status to give to animals (Staker, 2017). Reflecting this, different disciplines, including psychology (Dhont & Hodson, 2019; Loughnan et al., 2014), economics (Carlier & Treich, 2020), and philosophy (Singer, 1975) increasingly document moral double standards regarding animal treatment. Still, the *origins* of moral acrobatics relating to animals remain poorly understood. The present study seeks to provide some of the first evidence examining whether there are differences in the ways in which children and adults think about animal treatment.

It seems that as in other instances of moral conflict (Rochat, 2021), people solve their conflicted view of animals by engaging in deeply *categorical thinking*: people's judgements related to animals largely depend on *what* animal they are thinking about. Researchers have used stereotypes about animals to unveil categories of companions, predators, pests and prey (Sevillano & Fiske, 2016), while others still show that humans think about animal categories based on the threat or value different animals hold for humans (Hodson et al., 2014). Crucially, work has demonstrated that the *same* animal can be thought of differently depending on whether it is thought of as food or not (Bratanova et al., 2011). Relatedly, depending on whether a given animal is classified as food or not, people change their perceptions of how much "mind" an animal may have, even going so far as to disregard factual information about intelligence (Piazza & Loughnan, 2016). Together this evidence points to the importance of animal category membership. Think, for example, about pigs and dogs. Both are highly social and intelligent animals (Gerencsér et al., 2019) that do not differ in their ability to suffer. Yet, people treat these two animals very differently and perceive pigs to be less intelligent than dogs (Sevillano & Fiske, 2016).

The act of categorisation as food also plays an important role in determining an animal's moral value (Bratanova et al., 2011). Humans form a general *moral hierarchy* where some species are worthy of greater concern than others. There is a prevalent belief, "*speciesism*", that the moral worth of individuals is determined by their species membership (Caviola et al., 2019; Singer, 1975). Here, people not only distinguish between humans and animals, but also between different animal species (Caviola et al., 2019). For example, people show stronger acceptance of doing harm to pigs as compared to dogs, which is, in turn, related to their individual level of speciesism (Caviola et al., 2021). Crucially, different moral worth is attributed to different animal species despite participants being aware that these animals have the same intelligence and sentience (Caviola et al., 2019).

In sum, there are several interrelated psychological processes, both on the cognitive and motivational level, that are associated with moral acrobatics related to animals. First, such processes depend on categorising animals depending on their species, and second on the belief that membership of a particular species determines a living being's moral worth. Where does this come from? It is unknown when animal categorisation emerges and how speciesism is socially constructed throughout the developmental lifespan.

Like adults, children rely on social categories to understand the complexities of the world (Renno & Shutts, 2015; Shutts et al., 2013). From childhood on, humans identify the groups they belong to (e.g., gender and ethnic groups) and differentiate them from others (Nesdale, 2017). Further, 4-year-old children use physical features of animals to form distinct categories that different animals belong to (Meunier & Cordier, 2009), and 6-11-year-olds have been shown to group animals based on domesticity (Howard & Howard, 1977). In some cases, children's categorisations are related to preferences for these animals (e.g., when animals are similar to humans; Borgi & Cirulli, 2015), and 6-10-year-olds begin to rely on factors like edibility and perceived intelligence to inform evaluations of animals (Henseler Kozachenko & Piazza, 2021). Therefore, one possibility is that in late childhood children, like adults, grant moral worth based on species membership.

On the other hand, there is rich evidence that from an early age children are concerned with moral concepts including harm aversion (Decety & Cowell, 2018). Indeed, when asked about humans, children have been shown to prioritise moral concerns like fairness over category/group membership (Killen et al., 2013). Recent research suggests that children (5-9-years-old) are less likely than adults to prioritise human over animal lives in moral dilemmas (Wilks et al., 2021). Given this evidence it is also possible that, compared to adults, children's make similar moral judgements about living beings independent of the category the animal belongs to.

Here we examine whether some of the psychological processes that make moral acrobatics possible in relation to humans' treatment of animals are already apparent in childhood. In a preregistered series of tasks, we compare samples of children (9 – 11-years-old), young adults (18 – 21-years-old) and adults (29 – 59-years-old). These age groups allow us to examine developmental differences between youth and adults, along with any potential social differences between young adults (a particularly environmentally aware population; Wallis & Loy, 2021) compared to older adults.

We examine age-related differences across four key dependent variables; a) **Animal categorisation** (the likelihood of categorising a farm animal as food rather than as a pet), b) **Speciesism** (measured on a standardised speciesism scale), c) **Animal treatment** (evaluations of how farm animals ought to be treated as compared to pet animals and other humans), and d) **Food evaluation** (morally permissibility of eating animals and animal products). Given minimal evidence regarding how children categorize animals (for exceptions, see Howard & Howard, 1977; Meunier & Cordier, 2009), we approached age-related differences in the animal categorisation task as an open question. Based on existing evidence demonstrating higher aversion to harm towards animals in children (Wilks et al., 2021), we expected that children would demonstrate less speciesism than adults, state that farm animals ought to be treated better than adults would, and evaluate eating animals and their products as less morally acceptable. Potential age-related differences between young adults and adults were treated in an exploratory manner.

Methods

Open Science

The study was pre-registered on AsPredicted; <http://aspredicted.org/blind.php?x=2uu8fd> (children) and <https://aspredicted.org/blind.php?x=xn63v7> (adults). Materials and data are available at

https://osf.io/bea9m/?view_only=b9d75d7875464984bbc0f2190f5993cf. Our pre-registration specified the research questions, but not specific hypotheses. Our sample size was pre-registered and met for our three age groups although, due to the coronavirus lockdown, we were unable to collect our pre-specified adolescent sample. The measures used in the study were pre-specified. Our analyses were pre-specified with one exception. Rather than a multinomial logistic regression for our categorisation task (comparing farm animal categorisation into food, pet, or object as a function of age group) we carried out a binary logistic regression (comparing farm animal categorisation into food versus pet as a function of age group).

Ethics statement

The research was approved by the [BLINDED] Psychology Department ethics committee.

Sample

Four-hundred and seventy-nine participants (female $n = 275$, male $n = 198$, other gender $n = 2$, did not report gender $n = 4$) were recruited for this study. Participants were from three age groups; children ($n = 119$, $M \pm SD = 10.03 \pm 0.72$, 9-years-old - 12-years-old, female $n = 56$, male $n = 60$), young adults ($n = 181$, $M \pm SD = 19.09 \pm 0.85$, 18-years-old - 21-years-old, female $n = 103$, male $n = 76$), and adults ($n = 179$, $M \pm SD = 40.97 \pm 8.18$, 29-years-old - 59-years-old, female $n = 116$, male $n = 62$). Our sample was sufficient to detect a small effect size ($f = .15$) with an alpha of .05, power of .80, and four covariates (gender, diet, religion, animal ownership). Children were recruited from schools in a metropolitan area in the South of England. Children participated with parental consent and their own assent. Young adults were students at English universities, and adults were members of the general population recruited using Prolific Academic. All adult participants consented and were paid for their time.

Participants' ethnicity was as follows; White British ($n = 382$; 80%), Mixed Race/Dual Heritage ($n = 27$, 6%), South Asian British (including Bengali, Indian and Pakistani, $n = 16$, 4%), Black British ($n = 15$, 3%), Chinese British ($n = 2$, 0.4%), and Other ethnicities ($n = 26$, 5%). Eleven participants (2%) did not report their ethnicity. Eighty-four participants (18%) were vegan, vegetarian or pescatarian (within age groups; children – 13%, young adults – 22%, adults – 16%). The remaining 395 (82%) participants were omnivorous (within age groups; children – 87%, young adults – 78%, adults – 84%). Three-hundred and thirty-nine participants (71%) reported they were not religious and 134 (28%) reported religious affiliation. Three-hundred-and-one participants (63%) reported they had animals at home, whereas 176 (37%) participants did not have any animals at home. Analyses controlled for participant gender, diet, religious practice, and animal ownership. We ran analyses without these controls applied and observed the same results as reported.

Materials & Procedure

Children completed the survey either on a computer using online survey software Qualtrics, or in paper form. Once participants had been briefed, they completed the survey on their own and had the option to ask clarification questions throughout the procedure. Young adults and adults signed up for participation through Prolific Academic and completed the survey on Qualtrics.

Speciesism Scale

To measure speciesism, we adapted the six-item Speciesism Scale originally developed for adults (Caviola et al., 2019) to use language accessible to children as well as adult participants (full scale can be found in Appendix A). With this scale ($\alpha = .75$) we measured participants' belief that moral worth is determined by species membership (e.g., "it is okay to test new medicines on animals that we wouldn't test on humans" 1 = strongly disagree, 7 = strongly agree). For children, this scale was anchored at 1 with a thumbs down

graphic accompanying “strongly disagree” and at 7 with a thumbs up graphic accompanying “strongly agree”.

Categorisation Task

Participants were presented with five pictures including one farm animal (pig, cow, chicken), one companion animal (cat, dog, hamster), one animal food product (burger, bacon, chicken nuggets), one non-animal food product (banana, broccoli, tomato) and one unrelated object (watch, book, hat). They were asked to assign these items into one of three boxes labelled “food”, “pet” or “object”. Here we deliberately used a forced-choice paradigm with broad categories to gather clear early evidence on children’s *primary* categorisation of farm animals is when food is one possible category. Participants were given the prompt; “On this page you will see some different pictures. We want you to tell us what group these pictures belong to. If you think people eat what is shown in the picture, drag it to the ‘Food’ box. If you think people keep what is shown in the picture as a pet, drag it to the ‘Pet’ box. If you think what is shown in the picture is an object, drag it to the ‘Object’ box.”

Animal Treatment Task

The treatment task asked participants to evaluate how a range of targets are *usually* treated by humans and how they *should* be treated by humans. These questions were designed to tap into participants perceptions of the current status of human’s treatment of animals (i.e., ‘usually’) versus their perceptions of how animals ought to be normatively treated (i.e., ‘should’). The targets were rats (pest animal), chimpanzees (wild animal), dogs (companion animal), pigs (farm animal) and other humans. Participants were asked, “how well do humans usually treat [target]?” and “how well should humans treat [target]?” (1 = not well at all, 5 = extremely well). Participants responded to these questions for each of the five targets. The results for the analysis of the “usually” treated questions as well as the rats and chimpanzees are included as supplemental information.

Meat & Animal Product Evaluation

Participants were asked “how okay or not okay is it to eat animals?” and “how okay or not okay is it to eat things that come from animals, like eggs, milk or cheese?” (1 = really not okay, 6 = really okay). Previous work examining moral development of children and adolescents has asked about moral acceptability using scales of this type (e.g., Hitti et al., 2014).

Belief in Animal Minds

Additionally, we used a belief in animal minds measure adapted from Hills (1995) that included four statements (e.g., "Most animals are unaware of what is happening to them") that participants were asked to indicate their agreement with on a 6-point likert scale from 1 (not at all) to 6 (definitely, yes). As the scale demonstrated low reliability in our samples ($\alpha = .53$), we do not present results from this measure..

Data Analytic Plan

The categorisation task was assessed using binary logistic regression to examine the likelihood of categorizing the food animal as “food” or “pet”, as a function of participant age. The speciesism and meat/animal products evaluation tasks were assessed using univariate ANOVAs with participant age as a between-subjects factor. The animal treatment task was assessed using a repeated measures ANOVA examining differences in the within-subjects target factor (evaluations of dog, pig, human) as a function of participant age group. Simple effects testing using t-tests was carried out where appropriate.

Results

Animal Categorization

The binary logistic regression model with main effect of participant age was significant, $X^2(1) = 22.78, p < .001, \phi_c = .22$ (see Table 1). Participant age (1 = children, 0 = young adults / adults) was related to categorising a farm animal as food or as a pet, $\beta = 1.09$, Wald $X^2(1) = 22.78, p < .001$. To examine this further we conducted a chi-square analysis to compare farm animal categorization as food or pet across our three age groups. The results showed significant differences based on age group, $X^2(2) = 31.01, p < .001, \phi_c = .19$. Specifically, the difference between adults' categorisations (categorized as food $n = 132$, categorized as pet $n = 32$), differed significantly from that of children (categorized as food $n = 56$, categorized as pet $n = 53, p < .05$), but not from that of young adults (categorized as food $n = 116$, categorized as pet $n = 57, p > .05$). Thus, with age participants were more likely to categorize a farm animal as food than as a pet. The complete frequencies of each animal and their categorizations can be found as supplementary information, along with t-tests that document differences in our other dependent variables as a function of whether the participant categorized the farm animal as food or pet.

Table One. – Binary logistic regression analysis of participants’ categorization of farm animal (1 = food, 0 = pet)

Predictor	B	SE β	Wald's χ^2	df	p	e β (odds ratio)
Constant	-0.06	0.19	0.08	1	0.77	0.95
Age	1.09	0.23	22.78	1	0.001	2.97
Test			χ^2	df	p	
Overall model evaluation						
Likelihood ratio test			541.34	1	0.001	

Speciesism

We observed a main effect of age group in responses to the speciesism scale, $F(2, 459) = 14.03, p < .001, \eta_p^2 = .06$ (see Fig. 1 and Table 2 for descriptive statistics). Children’s speciesism values were lower than young adults ($t(293) = -4.70, p < .001$, Cohen’s $d = -.58$, LLCI = $-.72$, ULCI = $-.30$) and adults ($t(292) = -3.11, p = .002$, Cohen’s $d = -.38$, LLCI = $-.55$, ULCI = $-.12$). There was no difference between young adults’ and adults’ responses to this scale ($t(355) = 1.60, p = .11$, Cohen’s $d = .17$, LLCI = $-.04$, ULCI = $.38$). Hence, children show less speciesism than adults.

Table Two. – Speciesism scale descriptive statistics as a function of participant age group

300

301 **Animal Treatment**

302 **Across Age Group Comparisons**

303 When evaluating how humans should treat the targets, we observed a main effect of
 304 the target repeated measures variable, $F(4, 1804) = 24.54, p < .001, \eta_p^2 = .05$. This main
 305 effect was qualified by an interaction between the target and participant age group, $F(8,$
 306 $1804) = 11.11, p < .001, \eta_p^2 = .05$ (see Table 3 for descriptive statistics).

307

Table Three. – Treatment task descriptive statistics as a function of target and participant age group

	Human		LLCI	ULCI

Young Adults	3.97	0.92	3.83	4.07
Adults	4.17	0.81	4.06	4.29

Human

There was a difference between children's and young adults' ($t(290) = -2.16, p = .03$, Cohen's $d = -.26$, LLCI = $-.31$, ULCI = $-.01$) evaluations of how humans should treat other humans (see Fig. 2a). Young adults, compared to children, reported that humans ought to treat other humans better. There was no difference between children's and adults' reports ($t(289) = -1.62, p = .11$, Cohen's $d = .19$, LLCI = $-.26$, ULCI = $.03$), nor between young adults' and adults' reports ($t(355) = .67, p = .50$, Cohen's $d = .07$, LLCI = $-.08$, ULCI = $.16$).

319

Figure 2a. Evaluations of how well humans ought to treat other humans as a function of participant age group (1 = not well at all, 5 = extremely well; black dots represent mean per age group, with error bars representing 95% confidence intervals)

Dog

There were no observed differences between children's and young adults' ($t(292) = .64, p = .52$, Cohen's $d = .07$, LLCI = $-.09$, ULCI = $.19$), children's and adults' ($t(291) = .94, p = .35$, Cohen's $d = .10$, LLCI = $-.07$, ULCI = $.20$, or young adults' and adults' ($t(355) = .29, p = .77$, Cohen's $d = .03$, LLCI = $-.11$, ULCI = $.15$) responses to how well humans should treat dogs (see Fig. 2b).

Figure 2b. Evaluations of how well humans ought to treat dogs as a function of participant age group (1 = not well at all, 5 = extremely well; black dots represent mean per age group, with error bars representing 95% confidence intervals)

Pig

Children's evaluations of how humans should treat pigs were significantly higher than those of both young adults ($t(290) = 5.42, p < .001$, Cohen's $d = .69$, LLCI = .33, ULCI = .71) and adults ($t(289) = 3.76, p < .001$, Cohen's $d = .47, p < .001$, LLCI = .16, ULCI = .50). Young adults' evaluations were significantly lower than adults' evaluations ($t(355) = -2.15, p = .03$, Cohen's $d = -.23$, LLCI = -.38, ULCI = -.02) (see Fig. 2c). Hence, children perceived that farm animals ought to be treated better than both young adults and adults, whereas there are no age-related differences in how participants perceived companion animals and other humans ought to be treated.

Figure 2c. Evaluations of how well humans ought to treat pigs as a function of participant age group (1 = not well at all, 5 = extremely well; black dots represent mean per age group, with error bars representing 95% confidence intervals)

Within Age Group Comparisons*Children*

Children reported that dogs ought to be treated better than pigs ($t(111) = -2.60, p = .01$, Cohen's $d = -.27$, LLCI = $-.27$, ULCI = $-.04$) and humans ($t(111) = 3.26, p = .001$, Cohen's $d = .30$, LLCI = $.07$, ULCI = $.30$), but that pigs ought not to be treated differently from humans ($t(110) = .40, p = .69$, Cohen's $d = .05$, LLCI = $-.11$, ULCI = $.16$).

Young Adults

Young adults reported that pigs ought to be treated less well than dogs ($t(178) = -9.72, p < .001$, Cohen's $d = -.80$, LLCI = $-.75$, ULCI = $-.50$) and humans ($t(178) = -9.01, p < .001$, Cohen's $d = -.84$, LLCI = $-.79$, ULCI = $-.51$), but reported no difference between how well humans and dogs ought to be treated ($t(178) = -.40, p = .69$, Cohen's $d = .03$, LLCI = $-.13$, ULCI = $.09$).

Adults

Similarly, adults reported that pigs ought to be treated less well than dogs ($t(177) = -7.89, p < .001$, Cohen's $d = -.57$, LLCI = $-.51$, ULCI = $-.31$) and humans ($t(177) = -6.56, p < .001$, Cohen's $d = -.58$, LLCI = $-.53$, ULCI = $-.29$), but reported no difference between how well humans and dogs ought to be treated (mean was identical for each group). Hence, while children think that farm animals and humans ought to be treated equally well, by young adulthood and adulthood participants reported that companion animals and humans ought to be treated better than farm animals.

Meat & Animal Product Evaluation

We observed a main effect of participant age group on evaluations of how morally permissible it is to eat animals, $F(2, 457) = 22.94, p < .001, \eta_p^2 = .04$ (see Fig. 3 and Table 4). Children rated eating animals as significantly less permissible than both young adults ($t(291) = -5.39, p < .001$, Cohen's $d = -.65$, LLCI = -1.14 , ULCI = $-.53$) and adults ($t(290) = -4.12, p$

< .001, Cohen's $d = -.50$, LLCI = -1.03, ULCI = -.36). There was no difference between adults' and young adults' evaluations of eating animals ($t(355) = .98$, $p = .33$, Cohen's $d = .11$, LLCI = -.15, ULCI = .44). Hence, children perceive eating animals to be less morally permissible than young adults or adults do.

Similarly, we observed a main effect of participant age group on evaluations of how morally permissible it is to eat animal products (e.g. eggs, cheese, milk), $F(2, 458) = 7.40$, $p = .001$, $\eta_p^2 = .03$ (see Fig. 4 and Table 4). Children rated eating animal products as significantly less permissible than both young adults ($t(292) = -2.90$, $p = .004$, Cohen's $d = -.34$, LLCI = -.61, ULCI = -.12) and adults ($t(291) = -3.09$, $p = .002$, Cohen's $d = -.37$, LLCI = -.68, ULCI = -.15). There was no difference between adults' and young adults' evaluations of eating animal products ($t(355) = -.44$, $p = .66$, Cohen's $d = .05$, LLCI = -.28, ULCI = .17). Hence, children perceive consuming animal products to be less morally permissible than young adults or adults do.

Table Four. – Meat and animal product evaluation descriptive statistics as a function of participant age group

	Meat		LLCI	ULCI
	M	SD		
Children	3.35	1.29	3.03	3.50

428 **Within Subjects Correlations**

429 Correlations between our dependent variables are presented in full in online
430 supplemental materials. For young adults and adults, categorizing a farm animal as food
431 rather than as a pet was positively related to speciesism, negatively related to evaluations of
432 how well humans ought to treat pigs, and positively related to moral evaluations of eating
433 animals and eating animal products. Categorising a farm animal as food was not related to
434 evaluations of how well humans ought to treat other humans or dogs.

435 For children, categorizing a farm animal as food rather than as a pet was not related to
436 speciesism, evaluations of how well humans ought to treat other humans, dogs, or pigs, moral
437 evaluations of eating animals or moral evaluations of eating animal products. In contrast to
438 adulthood, in childhood the categorisation of animals as food was not yet related to views of
439 morality depending on species membership, moral evaluations of food or how well humans
440 ought to treat different animals.

441 **Table Five. – Correlations between dependent variables (Adults)**

	1	2	3	4	5	6	7	M	SD

 446 continuous variables, Pearson's R is reported

Discussion

Humans' relationship with animals is full of ethical double standards: some animals are beloved household companions, while others are kept in factory farms for economic benefit. Judgements seem to largely depend on the species of the animal in question: dogs are our friends, pigs are food. We found age-related differences that are consistent with the idea that such moral judgements are learned across the lifespan. Children showed lower speciesism compared to adults, i.e., a lower tendency to ascribe moral worth to individuals solely based on species membership. Moreover, with age participants were more likely to categorize a farm animal as food rather than as a companion animal. Further, children did not perceive pigs ought to be treated any differently than humans or dogs, whereas young adults and adults reported that dogs and humans ought to be treated better than pigs. Relatedly, older participants evaluated both eating animals and eating animal products as more morally acceptable than children did.

Modern factory farming often involves animal suffering, and research (Dhont & Hodson, 2019; Loughnan et al., 2014) is beginning to understand how humans reconcile this with their moral principles. Our findings demonstrate that children differ from adults in their categorization of animals and subsequent moral judgements: the process of attributing moral value based on species membership has not yet emerged by late childhood. Hence, it is with age that humans become more likely to categorize farm animals as food and appear to reconcile their eating habits and moral concerns by reporting that food animals ought not to be treated as well as other animals.

Many adult consumers are averse to harm against living entities yet accept food production systems involving harm to maintain their eating practices. To solve this inner moral conflict, adults have been shown to objectify food animals (Bastian & Loughnan, 2017; Bratanova et al., 2011) – attributing less intelligence, sentience, and ability to suffer. Our data

shows, in late childhood, children evaluate eating animals and animal products as less morally acceptable. Children may be less likely to objectify farm animals as demonstrated by their reduced likelihood of classifying animals as food. Hence, we can speculate that adults learn effective strategies to solve inner moral conflicts regarding animal treatment. This, however, does not warrant the conclusion that children simply see all animals as equal. To assess that possibility, we asked participants about animals that we could argue have particular moral standing in society, namely humans great ape cousins on the one hand (chimpanzees) and pests (rats) on the other (see supplemental information for results). We found that children think that chimpanzees ought to be treated better than pigs, and pigs better than rats. An important step in research will be to establish at what age, and why, children start to form moral hierarchies.

Along with examining the role of knowledge about food systems, future research is required to examine the emergent role of motivated cognition. Recent evidence has documented young children are less aware of which animals are eaten by humans (Henseler Kozachenko & Piazza, 2021). Research with adults has shown that motivations play an important role in whether people engage with information about animal sentience. For example, vegetarians and vegans see less difference between the intelligence of dogs and pigs (Bilewicz et al., 2011). Conversely, when omnivores are asked to justify their eating of animals, they view traits like intelligence as less morally relevant (Piazza & Loughnan, 2016). Future research is called to investigate how these different elements relating to animals' perceived moral value, that is categorisation as food, emergent knowledge of food systems, and motivated cognition relate to each other in a causal chain in children's cognition.

Here, our key age-related differences fell between childhood and young adulthood. Adolescence is possibly a developmental window where knowledge, social cognition and moral judgements coalesce to form the view that moral worth is determined by species membership and motivated cognition practices emerge. Extending the present examination into

497 adolescence will provide further support for the hypothesis that these categorisation processes
498 are socially constructed.

499 It is important to recognise the culturally bound nature of the present data. All data was
500 collected in the United Kingdom amongst a predominantly White British sample. While
501 consistent cross-cultural findings have been found regarding perceptions of animal's mental
502 capacities (Ruby & Heine, 2012), cultural norms regarding animal treatment vary across the
503 globe and work is needed that recognises this. This is especially pertinent in relation to
504 development, as differences in the impact of social norms on evaluation of eating meat and
505 animal products ought to be measurable in childhood when comparing samples from different
506 cultural contexts. Relatedly, widening the scope of the animal exemplars used in the study
507 would be an interesting future research direction – for example, do children make the same
508 judgments about cows and chickens as they do about pigs? Similarly, do children seen dogs as
509 a subtype of the 'pet' category worthy of even more moral concern than cats or hamsters for
510 example? From a methodological perspective, it will be important to extend the current
511 categorisation task to allow for multiple categorisations (e.g., seeing a chicken as both a pet
512 and food). This will provide important evidence regarding when children's own knowledge of
513 food systems begins to emerge and potentially conflict with their moral concerns.

514 Our research is a first attempt to understand the lifespan development of thinking about
515 animals and food. Our findings demonstrate differences and emerging commonalities in the
516 way children, compared to adults, think about non-human animals. Further understanding these
517 differences will play a crucial role in discussions regarding food, animals, and our environment
518 in educational settings. Human food production and consumption are related to timely global
519 issues like climate change (Gowri & Danielle, 2008). Attempts to mitigate these global
520 problems might benefit from open dialogues regarding our relationships with animals. The

evidence presented here suggests these dialogues ought to begin in youth when the social construction of the way humans think about animals begins.
