Abstract

An important finding in the cognitive effort literature has been that sensitivity to the costs of effort varies between individuals, suggesting that some people find effort more aversive than others. It has been suggested this may explain individual differences in other aspects of cognition; in particular that greater effort sensitivity may underlie some of the symptoms of conditions such as depression and schizophrenia. In this paper we highlight a major problem with existing measures of cognitive effort that hampers this line of research, specifically the confounding of effort and difficulty. This means that behaviour thought to reveal effort costs could equally be explained by cognitive capacity, which influences the frequency of success and thereby the chance of obtaining reward. To address this shortcoming we introduce a new test, the Number Switching Task (NST), specially designed such that difficulty will be unaffected by the effort manipulation and can easily be standardised across participants. In a large, online sample we show that these criteria are met successfully and reproduce classic effort discounting results with the NST. We also demonstrate the use of Bayesian modelling with this task, producing behavioural parameters which can then be associated with other measures, and report a preliminary association with the Need for Cognition scale.

Keywords: anhedonia, cognitive effort, computational psychiatry, depression, individual differences, new measures

1 Introduction

2 Cognitive effort, our ability to vary the depth of our engagement with a cognitive task,
3 influences a raft of fundamental cognitive processes including attention (Kahneman, 1973),
4 working memory (Westbrook et al., 2013), cognitive control (Braver, 2012; Shenhav,
5 Botvinick & Cohen, 2013) and decision-making (Ortega et al., 2015; Toplak, West &
6 Stanovich, 2011). Consequently, there is substantial interest in both measuring cognitive
7 effort and understanding the factors that determine when and how much effort is exerted in
8 different situations. Unfortunately, cognitive effort is challenging to study for the very same
9 reason – because it is so entangled with other processes, there is considerable potential for
10 confounding, and attempts to measure cognitive effort must therefore be careful to isolate
11 effort from other factors that may influence performance.

12
13 One particular problem—the conflation of effort and difficulty—has not to our knowledge
14 been addressed. Current methods for studying cognitive effort involve assessing participants’
15 preferences for different cognitive tasks: avoidance of more demanding tasks is interpreted as
16 evidence of underlying effort costs, and these are quantified by examining how participants
17 trade off the demand against rewards (a phenomenon termed effort discounting; see
18 Westbrook & Braver, 2015). However, more demanding tasks may also have lower rates of
19 success, and therefore of obtaining reward, giving rise to another form of discounting (this
20 time by the probability of reward) that would cause avoidance of the more demanding tasks
21 in exactly the same way.

22
23 Consider for example the N-back working memory task, which is frequently used in studies
24 of cognitive effort (see e.g. Westbrook et al., 2013). Higher levels of the N-back feel more
25 effortful, but they are also intrinsically more difficult to perform accurately, because with

more items to hold in memory, the maximum precision with which each item can be maintained is lower (Bays, Catalao & Husain, 2009). If we observe discounting of the value of the task as the N-back level increases, it is impossible to say to what extent this is due to the greater effort required or the lower probability of completing a trial successfully and gaining reward. Similar arguments can be made for other effort manipulations, including visual attention (e.g. Apps, 2015), auditory attention (e.g. McLaughlin et al., 2021; Crawford, Eisenstein et al., 2022) and response conflict tasks (e.g. McGuire & Botvinick, 2010; Schmidt et al., 2012). This confounding may cause overestimation of participants' cognitive effort sensitivity (because both effort and probability discounting are contributing to the observed behaviour). In order to dissociate these processes, it is essential that measures of cognitive effort hold difficulty constant when manipulating task demand.

It is important too that the difficulty of the task can be standardised across participants, as is usual in tasks manipulating physical effort (Chong et al., 2016; Husain & Roiser, 2018). For example, in physical effort tasks measuring grip strength (e.g. Bonnelle et al., 2016), the different levels are typically normalised relative to participants' maximum grip force, so that while the absolute difficulty of the task (the grip force required) may differ between participants, the relative difficulty (the proportion of maximum capacity required) is held constant; crucially, therefore, participants are all able to achieve comparable levels of performance. Likewise, in cognitive effort tasks, we need to take account of baseline differences in cognitive capacity (for example, differences in working memory capacity or processing speed). In tasks that do not standardise the difficulty, the problem of confounding again rears its head – if two participants apparently differ in the subjective value they ascribe to a task, we cannot say to what extent this reflects genuine differences in sensitivity to effort, as opposed simply to differences in the probability of achieving success. This is a particular

concern with regards to psychiatric research into conditions such as depression and schizophrenia, where cognitive impairment is a core symptom (Mesholam-Gately et al., 2009; Rock et al., 2014) and therefore patients are likely to find the task fundamentally more difficult than healthy controls.

Some attempts have been made previously to take account of this issue. For example, Westbrook et al. (2013) statistically control for the effect of performance on subjective value in a regression model. However, this involves conditioning on a variable (performance) which is causally posterior to the outcome variable of the regression (subjective value). It is better to standardise the task itself, but to our knowledge this has been attempted only once before, by Ang et al. (2022), who devised a task they called the Cognitive Effort Motivation Task (CEMT). Ang et al. probed effort by asking participants to remember the location of one or more squares on a checkerboard, and normalised the difficulty for each participant by reducing the total number of squares on the grid until they could achieve at least 80% accuracy during a training phase. However, although the CEMT has resolved the issue of confounding between participants, it still suffers from confounding *within* participants – as with the N-back task discussed above, higher demand levels in the CEMT give participants more information to hold in memory, such that both effort and the intrinsic difficulty of the task covary.

A new cognitive effort measure – the Number Switching Task

The purpose of the present study was therefore to develop a task that distinguishes cognitive effort discounting from probability discounting completely. Specifically, we targeted two main criteria: the manipulation of effort demand should not affect the probability of success; and it should be possible to standardise the task difficulty by reference to each participant's

1 baseline ability. While other tasks have been able to satisfy one or other of these criteria, the
2 key significance of our task is that it meets both of them. Two further considerations were
3 that the task should have several levels of effort demand, so that we could examine
4 parametric responses to the manipulation across a reasonable dynamic range, and also that it
5 should be optimised for use online, where it is possible to obtain much larger sample sizes
6 more practically than through in-person testing.

7
8 We developed the Number Switching Task (NST), which involves categorising each digit in
9 a nine-digit sequence as either even or odd. By changing the frequency of switching between
10 odd and even we can manipulate the effort required but, crucially, it is only the order of the
11 digits that changes – the actual content of the trials is all the same. This means that regardless
12 of effort level, participants are completing the same set of operations on every trial, so the
13 difficulty of the task—the information processing demands—is held constant (this
14 distinguishes the NST from working memory based effort tasks, in which higher effort levels
15 contain more information content to remember). Significantly, in the NST we can also
16 standardise the difficulty of the task, by calibrating the time participants are allowed to
17 complete each sequence, such that all participants are capable of achieving comparable levels
18 of success.

19
20 Note that while this task is superficially similar to the Demand Selection Task (Kool et al.,
21 2010), which also involves categorising digits, the manipulation of effort is rather different:
22 the Demand Selection Task employs a Stroop-like structure of switching between different
23 response rules, whereas in the NST it is the switching between odd and even itself that is
24 effortful. This means that while the Demand Selection Task only compares two conditions,
25 high vs. low switching, the NST is capable of measuring a wider range of effort levels (here

we use 4 effort levels). In addition the NST allows us to examine the interacting effect of reward on participants' choices, unlike the Demand Selection Task which probes effort alone.

The primary aim of this study was to validate the NST by testing the prediction that the effort manipulation will elicit the classic effort discounting effect without affecting the difficulty as measured by the rate of success. We also present some secondary analyses including Bayesian modelling and an assessment of preliminary associations with cognitive traits relevant to depression and anhedonia.

Method

Preregistration

This study was preregistered on the Open Science Framework (doi:10.17605/OSF.IO/8Y7P9). There were no deviations from this plan.

Participants

Participants were recruited through the online platform Prolific (www.prolific.co/). To be eligible, they had to be aged 18-60, with no history of a diagnosed mental health condition, and could not have taken part in any of the pilot experiments for this study. They also had to use a computer – smartphones or tablets were not allowed.

In our preregistration we calculated a minimum required sample size of 259 participants in order to detect an effect of $r = .2$ with 90% power and $\alpha = .05$ (two-tailed). We recruited more than this, to allow for withdrawals and exclusions, so that the sample included 306 participants who completed the experiment. Of these, three were excluded because they refreshed the web page part way through; nine were excluded because they repeatedly failed the familiarisation phase of the effort task; and four were excluded because they failed attention checks in the questionnaires. This left 290 participants with data included in the final analysis. The age and education distribution of this sample is provided in Table 1.

Table 1. The age and education distribution of participants.

Age group	N

Master's Degree	58
PhD	7

Procedure

From Prolific, participants were automatically directed to another website, Gorilla (www.gorilla.sc/), where the study was hosted. There they completed the Cognitive Effort Task, followed by eight questionnaires. At the end of the study, they were redirected back to Prolific via a unique URL, which allowed them to prove they had completed all the tasks; if instead they returned to Prolific manually (without this URL), their data was flagged and we checked whether they had actually completed all the tasks or not. On average, the entire study took approximately 45 minutes, from signing up to returning to Prolific, and participants

were paid a flat rate of £5 plus a performance bonus of 1 pence per 3 points won on the effort task (on average participants won around £1.50 in bonuses).

The Number Switching Task

The structure of the task is shown in Figure 1. On each trial, participants were offered a reward (3, 6, 9 or 12 points, corresponding to 1, 2, 3 or 4p of real money, respectively) to complete an effortful task with a specified level of demand. If they accepted this challenge they had to complete the task successfully to win the reward; if they rejected it, they avoided performing the task, but won no points and, after a timeout of 2500ms, proceeded to the next offer.

The effortful task itself was to categorise each of the digits in a random sequence of the numbers one to nine as either odd or even. The effort of this task scales with the frequency of switching between odd and even digits, allowing us to define four levels of demand: the lowest level, referred to in the task as 20%, contained either 1 or 2 switches; the next level (40%) 3 or 4 switches; the 60% level 5 or 6 switches; and the highest level, 80%, had 7 or 8 switches. On any given trial, the precise number of switches was determined at random to prevent the sequences becoming predictable. Participants were not explicitly told about the relationship between effort level and number of switches but instead learned this over the course of the familiarisation and main phases of the experiment.

1

Figure 1. *Number Switching Task trial structure*. Participants chose whether or not to perform an effortful task depending on the points and effort level offered. If they accepted the offer, they were shown a random sequence of the digits 1-9, and had to indicate (by pressing the ‘f’ or ‘j’ keys) whether each of the digits was even or odd. Sequences with more frequent switching between odd and even were more effortful. To win the points on offer, participants had to categorise at least 8 of the 9 digits correctly and complete the sequence within the allowed time (which was calibrated to each individual). In the above figure, the ‘alternative outcomes’ show screens that participants saw if they passed an offer, or if they failed the trial owing to too many errors or timing out.

2

3 As each digit appeared on the screen in sequence, participants responded, as soon as they saw
 4 the digits, using the ‘f’ and ‘j’ keys to indicate whether it was ‘odd’ or ‘even’ (key mapping
 5 was counterbalanced across participants). Instructions about these responses were provided
 6 on an instruction screen at the start of the task. While the individual categorisations were self-
 7 paced, meaning the next digit did not appear on the screen until a response had been made to
 8 the current item, there was a time limit for completing the overall sequence. A trial was

marked as 'correct' only if the sequence was finished within this limit and with no more than one wrong response. 'Incorrect' sequences were not rewarded.

Importantly, this allowed us to standardise the difficulty across participants: by calibrating the allowed time based on performance during an earlier familiarisation phase, we ensured that all participants had similar success rates on the task.

Phases of the task

Prior to embarking on the full task, participants progressed through instructions and practice rounds, followed by a longer familiarisation phase. This latter phase was used to calibrate the time limit for the sequences in the main phase of the task. See Figure 2.

Figure 2. Overall structure of the different phases of the task. See main text for detailed description of each phase.

2

3 The instruction phase informed participants which keys they should press to categorise each

4 digit as even or odd. Then, in an initial practice round, they were shown a sequence of the

5 digits one to nine in ascending order, and they had to categorise all of these correctly to

6 continue; if they made a single mistake, this round was repeated. We thus ensured that

7 participants' keys were working and that they understood the basic premise of the task.

8 Unlike in the later, main phase of the task, here there was no time limit for completing the

9 sequences. In addition, after participants gave their response the digits changed to green or

10 red to indicate whether the response was correct or not (unlike in the main phase of the task

11 where participants only received feedback at the end of the sequence).

1 The subsequent familiarisation phase was similar—participants completed a set of 32
2 sequences, again without the offer framing or the time limit—but now the digits were
3 presented in a randomised order. This phase comprised four trials of each of the eight
4 possible numbers of switches. Although there was no time limit, participants were now
5 instructed to respond as quickly as possible while still trying to complete each sequence
6 correctly.

7
8 To progress through the familiarisation phase to the main task, participants had to achieve at
9 least 50% correct responses on the most difficult 8-switch trials; if they failed more than 50%
10 of these trials they were given one opportunity to repeat this stage; if they failed again they
11 were excluded.

12
13 For participants who passed the familiarisation phase, we calculated their time allowed for
14 the main phase sequences as the median time to complete the hardest, 8-switch trials plus
15 500ms. During piloting we observed that this provided a good balance between providing
16 sufficient time pressure to elicit the effort effects while ensuring that the task was possible
17 within the maximum completion time for all participants.

18
19 Finally, participants completed the main phase of the task, in which the full trial structure was
20 used (as depicted in Figure 1). After 10 example trials in which participants were introduced
21 to and gained experience with the offer framing, the main phase itself comprised a total of 80
22 trials – five trials of each of the 16 possible offer combinations, in a random order.

Questionnaire measures

Following the NST, participants completed a number of questionnaires. In all cases, participants gave their responses by moving a horizontal slider (which defaulted to the centre).

First was the NASA Task Load Index (Hart & Staveland, 1988), henceforth the ‘Subjective Task Load’, which asked participants to give their subjective rating (over six subscales) of the level of demand felt while performing each of the effort levels in the task. Subsequently there were seven questionnaires assessing different traits: the Cognitive Complaints Inventory (Iverson & Lam, 2013), the Fatigue Severity Scale (Krupp, LaRocca, Muir-Nash & Steinberg, 1989), the International Physical Activity Questionnaire Short Form (Lee, Macfarlane, Lam & Stewart, 2011), the Need for Cognition six-item scale (Coelho, Hanel & Wolf, 2018), the Temporal Experience of Pleasure Scale (Gard, et al. 2006) and the Zung Depression Scale (Zung, 1965). Further detail on these questionnaires and their scoring is provided in the Supplement.

We appended catch questions (e.g. “Select ‘very much’ for this question”) to two questionnaires, the Cognitive Complaints Inventory and the Need for Cognition Scale, to identify participants who were not paying attention. We placed these at the end of the questionnaires to avoid interfering with the psychometric properties of the measures themselves.

Statistical Analyses

Preregistered analyses

The main dependent variable on the NST was the proportion of offers accepted for each combination of reward and effort level. We also recorded participants' accuracy and completion times for the odd/even categorisation task – these were of course conditional on participants accepting the offer in the first place and, in the case of the completion times, completing the sequence within the time allowed and with no more than one mistake allowed.

Our primary analysis was a multilevel (mixed effects) ANOVA. This was used because multilevel ANOVAs can accommodate unbalanced designs, which arise in this task because participants could choose to accept or reject trials at will, resulting in secondary measures (success rate and completion time) with different numbers of trials from each participant. These ANOVAs contained fixed effects of reward and effort and their interaction, and varying intercepts across subjects.

For analysis of the Subjective Task Load questionnaire, six multilevel ANOVAs were constructed, one for each of the constituent scales of the index, using a fixed effect of effort level and varying intercepts across subjects.

Throughout these analyses, we further investigated any significant effects indicated by the ANOVAs using post-hoc simple effects ANOVAs and paired-samples *t*-tests as appropriate. Note that, unlike the multilevel ANOVAs, the *t*-tests require complete cases. This results in differing degrees of freedom across analyses, as some participants had to be excluded from specific post-hoc analyses of success rates or completion times if they had not completed any trials at a particular reward or effort level.

Exploratory analyses

Bayesian Modelling

We considered twelve models, all variations on a logistic regression, listed in Table 2. The characteristic mathematical form of these models is provided in Equation 1. This particular set of equations represents Model 9 – all of the other models can be constructed by modifying one or more components of this model.

Equation 1:

$$Y_{subject,trial} \sim \text{Bernoulli}(p_{subject,trial})$$

$$p_{subject,trial} = \text{logistic}(\alpha_{subject} + \beta_{linear_reward,subject}reward_{trial}$$

$$+ \beta_{quad_reward,subject}reward_{trial}^2 + \beta_{effort,subject}effort_{trial})$$

where $y_{subject,trial} \in \{0,1\}$ is the choice of a particular subject on a particular trial to accept or reject the challenge. The underlying probability of accepting an challenge, $p_{subject,trial}$, is then calculated as a logistic function of a linear combination of a number of parameters, typically including an intercept, α , and one or more effects of reward and effort, β_{reward} and β_{effort} respectively.

In Equation 1, the intercept and effects vary across subjects; however, as noted in Table 2, in some models these parameters were fixed instead, meaning all subjects took the same value.

Table 2. Specification of models fitted to the Number Switching Task. We fitted and compared twelve models in total, containing different terms. I = intercept, R = reward, E = effort. The prefix f or v indicates whether this term was fixed (one parameter estimated for the whole population) or varying (individual effects estimated for each participant, constrained by a hierarchical prior).

Model	
1	fI
2	fI + fR + fE
3	vI + fR + fE
4	vI + vR + vE
5	fI + fR + fE + fE^2
6	vI + fR + fE + fE^2
7	vI + vR + vE + vE^2
8	vI + vR + vE^2
9	vI + vR + vR^2 + vE
10	vI + vR^2 + vE
11	vI + vR + vR^2 + vE + vE^2
12	vI + vR^2 + vE^2

The subject-level parameters were all given hierarchical priors which were determined through a process of prior predictive checking. Details are given in the Supplement.

We standardised the values of the predictors (the reward and effort levels), for computational and arithmetical simplicity. Note that this affects the interpretation of absolute parameter values from the model.

The models were fitted using Markov Chain Monte Carlo simulation in Stan (Stan Development Team, 2021). Sampling was run for four chains each with 1000 iterations. Subsequent to fitting, we carried out the recommended standard diagnostics (visual inspection of the chains, no divergences or treedepth warnings, E-BFMI < 0.3, effective sample size > 400, split- $\hat{R}$ < 1.01; Betancourt, 2018) and found no issues. We also inspected

the posterior predictions for the winning model and observed a good overall fit to the data (see Figure S7).

Structural Equation Modelling

We used confirmatory factor analysis (CFA) to fit several potential factor structures to the questionnaire data. We identified the best-fitting structure and inserted this into a structural equation model (SEM), with which we sought to predict the behavioural parameters estimated for each subject (intercept, reward and effort sensitivity) from their cognitive trait scores.

Computing environment and packages

Analyses were conducted in R version 3.5.3 (R Core Team, 2019). We used the R package ‘lme4’ (1.1-21; Bates et al., 2015) to fit the multilevel ANOVAs and ‘rstatix’ (0.6.0; Kassambara, 2020) to conduct the post-hoc tests. Bayesian models were fitted in Stan using CmdStanR (0.3.0, Gabry, & Češnovar). SEM was conducted in Lavaan (Rosseel, 2012).

1 Results

2 Preregistered Analyses

3 Number Switching Task

4 *Proportion of Offers Accepted*

5 The proportions of offers accepted at each level of reward and effort are plotted in Figure 3.

6 These show a significant reward-by-effort interaction, $F(1, 4347) = 30.8, p < .001$,

7 $\eta^2_{\text{partial}} = .04$, consistent with participants treating the effort level as an economic cost.

8 Specifically, the value of a reward was progressively discounted as the effort required to

9 obtain it increased, but this discounting was shallower when the reward offered is greater.

10 Despite this flattening as reward increased, the effort effect was still significant at every

11 reward level in post-hoc ANOVAs (all $ps < .001$). The main effects of reward and effort were

12 also both significant, $F(1,4347) = 108, p < .001$, and $F(1,4347) = 84.4, p < .001$ respectively.

13 Full descriptive statistics are provided in Table S1.

Figure 3. *Number Switching Task: proportion of offers accepted.* Figure shows the mean, standard error and distribution of the proportion of offers accepted for each combination of reward and effort level. See also Figure S9 for the same plot without faceting.

Success Rate

The success rate for each level of reward and effort is plotted in Figure 4. The only statistically significant effect was that of reward, $F(1, 4024) = 68.1, p < .0001, \eta^2_{\text{partial}} = 0.08$, with participants more likely to complete the sequence correctly as the offered reward increased (Table 3), consistent with higher rewards being more motivating. Post-hoc t -tests indicated that this was driven primarily by the increase in success rates between the 3 and 6 point reward levels, $t(272) = 3.01, p = .008, d = 0.18$, while the differences between 6 and 9 points, and 9 and 12 points did not achieve significance after Bonferonni-adjusting for multiple comparisons ($ps = .10$ and $.07$, and, $ds = 0.13$ and 0.14 , respectively). Full descriptive statistics are provided in Table S2.

The effort level had no significant effect on the success rate, $F(1, 4024) = 2.18, p = .14$, and the reward-by-effort interaction was also non-significant, $F(1, 4024) = 0.380, p = .54$.

Importantly, the success rate varied relatively little across participants (overall mean = 0.90, SD = 0.11), suggesting the standardisation of difficulty had been successful.

Table 3. Number Switching Task: Descriptive statistics for the proportion of trials completed successfully (across reward levels).

P(Success)		
Reward (points)	N	Mean (SD)
3	273	0.86 (0.18)
6	273	0.89 (0.12)
9	273	0.91 (0.10)
12	273	0.92 (0.10)

Note. To be marked as correct, sequences had to be completed within the time limit and with no more than one error. These data only include complete cases, i.e. where participants attempted at least one trial for each level of reward. SD=standard deviation.

Figure 4. Number Switching Task: proportion of trials completed successfully. Figure shows the mean, standard error and distribution for each combination of reward and effort level. Trials were marked as ‘correct’ if they were completed within the allowed time, with no more than one error. See also Figure S9 for the same plot without faceting.

Completion Times

Completion times, expressed as a proportion of each participant's maximum allowed time, are plotted in Figure 5. Full descriptive statistics are provided in Table S3. The overall mean (SD) maximum allowed time was 8953ms (1700ms). There were significant main effects of both reward, $F(1, 4014) = 10.1, p = .002, \eta^2_{\text{partial}} = .03$, and effort, $F(1, 4014) = 610, p < .001, \eta^2_{\text{partial}} = .52$. The interaction effect was non-significant, $F(1, 4014) = 0.56, p = .45$. We further investigated the two main effects with three post-hoc t -tests for each factor. The p -values reported are Bonferroni-adjusted for multiple comparisons.

For the main effect of effort, we observed a curved pattern, with completion times lengthening progressively as the effort level increased between 20% and 60%, before decreasing again slightly for the 80% effort level (see descriptive statistics in Table 4). The contrasts between adjacent effort levels were all significant (20% vs 40% effort: $t(286) = 19.7, p < .001, d = 1.16$; 40% vs 60% effort: $t(286) = 7.07, p < .001, d = 0.42$; and 60% vs 80% effort: $t(286) = 8.88, p < .001, d = 0.52$).

For the main effect of reward, the descriptive statistics (see Table 4) suggested that completion times decreased slightly with increasing reward level, although the post-hoc comparisons between adjacent reward levels were all non-significant following Bonferroni correction (3 vs 6 points: $t(272) = 0.08, p = 1.0$; 6 vs 9 points: $t(272) = 1.11, p = .80$; 9 vs 12 points: $t(272) = 2.32, p = .06$).

Finally, in a further, exploratory analysis we also examined whether there was a significant association between participants' maximum allowed time and the six questionnaire measures; however, none of these were significant (all $ps > .05$).

Table 4. Number Switching Task: Descriptive statistics for proportional completion time (across reward and effort levels).

Proportional Completion Time		
Reward (points)	N	Mean (SD)
3	273	0.84 (0.06)
6	273	0.84 (0.05)
9	273	0.84 (0.05)
12	273	0.83 (0.05)
Effort Level		
20%	287	0.80 (0.07)
40%	287	0.85 (0.06)
60%	287	0.86 (0.05)
80%	287	0.84 (0.05)

1

2

Notes. Times are expressed as a proportion of each participant's maximum allowed completion time.

3

These data only include complete cases, i.e. where participants recorded at least one trial for each level of

4

reward or points.

5

6

7

Figure 5. *Number Switching Task: completion time*. Figure shows the mean, standard error and distribution of the completion times (expressed as a proportion of each participant's allowed time) for each level of reward and effort level. See also Figure S9 for the same plot without faceting.

Subjective Task Load

Participants' ratings of the subjective demand of each effort level are shown in Figure 6, with each scale of the index plotted in a separate panel. Participants reported that they found each effort level successively more demanding, which was confirmed statistically (all ANOVAs indicated a significant effect of effort, $ps < .0001$). Post-hoc t -tests of the differences between sequential levels of effort are reported in Table 5. These comparisons were all significant (after Bonferroni correction), except for one: the comparison between ratings of perceived performance on the 60% and 80% effort.

Table 5. Subjective Task Load: post-hoc <i>t</i> -tests and standardised effect sizes.									
	Effort Level Comparisons

3

freedom are 289 throughout.

Figure 6. *Subjective task load ratings for each effort level.* Plots show (from left to right within each plot) the individual data points, the means and standard errors and the distributions of scores for each of the six scales of the index.

Exploratory Analyses

Model Comparison

We started by comparing the twelve models using the Widely-Applicable Information Criterion (WAIC; Watanabe, 2010). WAIC estimates the out-of-sample predictive accuracy of a model, providing both a point estimate and standard error, enabling us to quantify uncertainty.

The WAIC values for the three best scoring models are plotted in Figure 7. The best model was Model 9 ($vI + vR + vR^2 + vE$), so we proceeded with the rest of the modelling analysis using the posterior estimates from this model. The distance to the next two models, Model 4 ($vI + vR + vE$) and Model 7 ($vI + vR + vE + vE^2$) was fairly large but not definitive (3.2 and 3.3 standard errors respectively), so we also conducted sensitivity analyses using these two models, which are reported in the Supplement. There were no major differences between the inferences drawn from any of these models.

Figure 7. *Differences in WAIC relative to the best performing model (Model 9). Also shown is the standard error of this difference (black intervals). For simplicity, only the three best scoring models are shown above; the full plot of all eight models is given in Figure S6. Model 9, the best performing model, contained a varying intercept, varying linear effects of reward and effort and a varying quadratic effect of effort.*

Figure 8 shows the posterior estimates of the population-level intercept, reward and effort sensitivity parameters (mean and standard deviation). Note that none of these overlap zero, indicating that, as we would expect, participants are sensitive to both reward and effort (in accordance with the earlier ANOVA results).

Figure 8. *Posterior distributions of the population level parameters from Model 9 ($vI + vR + vR^2 + vE$). The vertical line indicates the mean of each distribution and the shaded region the 89% quantile interval.*

1 The posterior predictions of the model are shown in Figure S7. First, we see that the model
2 predicts that the probability of accepting a challenge will decrease as a concave function of
3 effort level and that this decline will be progressively shallower at higher levels of offered
4 reward. This means that this model is able to reproduce not just the basic discounting of
5 reward by effort, but also the specific shape of the discounting curves observed in the data.
6 Secondly, the models also clearly show substantial uncertainty about the exact relationship
7 between the probability of accepting a challenge and effort when it comes to predicting
8 individual participant behaviour. In other words, the average population-level effect is clear
9 but the model implies there is substantial variability between individuals.

10
11 Next, we examined the correlation between the participant-level effort sensitivity parameters
12 and the probability of success on the task (see Figure 9). Importantly, this was not
13 significantly different from zero, $r(288) = 0.10$, $p = .09$, suggesting effort sensitivity was not
14 confounded by probability discounting.

Figure 9. *Relationship between the probability of success and effort sensitivity.* The correlation was non-significant ($p = .09$), implying that effort sensitivity is not confounded by probability discounting in this task. **Note** the extreme point on the left of the graph corresponds to a participant who accepted (and failed) only one trial overall. In a sensitivity analysis, removing this participant increased the p -value of the correlation to $p = .14$.

1

2

3 Association of computational parameters with questionnaire measures

4 The purpose of this final stage of our analysis was to explore any associations between the

5 traits assessed by our questionnaires and the subject-level parameters estimated in Model 9

6 above ($vI + vR + vR^2 + vE$).

7

8 As an exploratory step we first conducted a series of regressions looking at each

9 questionnaire individually (controlling for age and education each time). We found

10 significant associations between effort sensitivity and Cognitive Complaints ($\beta = 0.02$,

11 $p = .04$), Fatigue Symptoms ($\beta = 0.01$, $p = .04$), Need for Cognition ($\beta = -0.02$, $p = .02$), and

12 Zung Depression Score ($\beta = 0.01$, $p = .04$). The remaining associations were non-significant:

Experience of Pleasure ($p = .90$), and Physical Activity ($p = .53$). With regards to linear reward sensitivity we found an association with Need for Cognition ($\beta = 0.04$, $p = .03$), as well as with Physical Activity ($\beta = -0.17$, $p = .03$), but not the other questionnaire measures. Finally, there were no significant associations with any of the questionnaires for either quadratic reward sensitivity or the intercept parameter. Note we have not corrected for multiple comparisons; we therefore emphasise that the above results should be treated as indicative and exploratory only.

To mitigate the multiple comparisons problem and provide a complementary means of assessing these associations, we had also planned a structural equation modelling analysis – this allowed us to test all of the associations at the same time, therefore without requiring correction. First, we used confirmatory factor analysis to compare several possible factor structures which were devised *a priori*. The CFA is described in detail in the Supplement; briefly, the four structures considered were:

- One with a distinct latent factor for each questionnaire
- Another in which the all questions mapped onto a single latent factor, equivalent to a ‘P’ factor in psychiatry (Caspi et al., 2013)
- A structure in which they were grouped by broad cognitive domain
- Another in which the questionnaires directly relevant to mental health symptoms were grouped together

We found the ‘full’ structure (i.e. with a distinct latent factor for each questionnaire) fitted the data best.

We then conducted an SEM, using this full factor structure as the measurement model, to predict the subject-level intercept, reward and effort sensitivity parameters obtained from Model 9 ($vI + vR + vR^2 + vE$) of the Number Switching Task. This time we found a significant positive association between Need for Cognition and both the linear and quadratic reward sensitivity parameters (standardised $\beta = 0.29, p = .003$, and $\beta = 0.06, p = .03$ respectively). However, all other associations were non-significant. A possible reason for the discrepancy between this result and those from the simple regressions detailed earlier is that the SEM regression measures the unique variance explained by each latent factor, whereas in fact several of the factors may be making a shared contribution to effort sensitivity. One clue that this is the case is that, in the SEM, the latent factors for cognitive complaints, fatigue, need for cognition and depression symptoms all significantly covaried with one another. Full results from the SEM regression are provided in Tables S5 and S6.

Ruling out temporal discounting effects

One possible issue with the NST is that, because participants were allowed different times in which to complete the sequences, they may experience different rates of reward, in turn introducing temporal discounting effects. To test for this, we examined the association between participants' probability of accepting each level and their average time taken to complete that level – if their choices were affected by temporal discounting we would expect to see a negative correlation, with lower probability of accepting an offer as the duration increases. However, there was no significant association, $r = 0.002, t(4304) = 0.13, p = .89$, suggesting temporal discounting did not affect participants' choices. In a complementary analysis we also tested the correlation between participants' overall tendency to accept (the intercept parameter estimated by Model 9) and their allowed time; again this was non-

1 significant, $r = -0.03$, $t(0.53)$, $p = .59$. Further tests of the correlations between allowed time
2 and other variables are included in the Supplement, Table S7.

3

Discussion

We have presented a new task, the NST, for measuring cognitive effort and demonstrated that it resolves one of the major shortcomings of existing measures, namely the confounding of effort by task difficulty. In our results, obtained from a large online sample, participants treated higher effort levels as more costly, despite being just as likely to win the offered reward. The idea that cognitive effort is costly is one of the foundational assumptions of cognitive effort research, and is supported by earlier studies showing effort discounting in several contexts (Apps et al., 2015; McLaughlin et al., 2021; Crawford, Eisenstein et al., 2022; Crawford, English et al., 2022; Kool et al., 2010; Kool & Botvinick, 2014; Westbrook et al., 2013); importantly, however, this is the first time that effort discounting has been studied in a task where effort and difficulty are not confounded. In other words, we were able to manipulate and measure cognitive effort without the problem of probability discounting.

A related concern was that we need to be able to standardise the difficulty of the task, otherwise comparisons across participants (for example between patient groups and healthy controls), may not be valid. In the NST this is achieved by tailoring the time allowed for completion of each sequence to participants individually. Encouragingly, the success rates were very consistent across participants, suggesting the standardisation procedure was successful.

The finding that completion times generally became longer as the effort level increased is consistent with these levels requiring more cognitive control (and therefore effort; Shenhav et al., 2017), but the small reduction in completion time at the highest level was unexpected. This is mirrored by a similar, though non-significant, increase in accuracy at the highest effort levels. The most likely explanation is that half of the sequences at this level involved

alternating on every digit (i.e. eight switches), which, even though participants could not be sure exactly how many switches they would be shown, may have permitted them to respond slightly faster and/or more accurately. If so, this should be straightforward to address – future iterations of this task could use a ten- rather than nine-digit sequence, so that sequences which alternate on every digit are no longer possible. This would have the further advantage of requiring one digit to be shown twice, making it impossible for participants to work out which digits remain to be shown.

A key component of the NST's design is that the time allowed to complete the nine-digit sequences is personalised to each participant. This allows us to normalise the difficulty of the task and adjust for differences between participants in cognitive capacity; however, it also introduces the potential for temporal discounting, since participants may experience different rates of reward. Fortunately we were able to rule out effects of temporal discounting in our results; we found that there was no association between participants' effort sensitivity and the time they were had to complete the sequences. Thus we can be relatively confident that the NST is measuring effort discounting rather than temporal discounting.

One last feature of the NST results that deserves comment is the observation that the acceptance rates are relatively high (averaging over 50%) across all of the conditions. This is by design – the task needed to be suitable for use with patients, who are likely to have much lower acceptance rates than the healthy participants we have initially tested here. Nevertheless, if in future studies the acceptance rates are seen to be too high then a possible change might be, for example, to offer a low reward/low effort alternative during the choice phase, rather than the current accept/reject choice. This could also permit calculation of subjective indifference points if desired.

1 The Subjective Task Load results show clearly that participants reported finding each level of
2 effort progressively more demanding. The increase in physical demand at higher effort levels
3 is a potential issue, as participants should in theory be making the same number of key
4 presses at approximately the same rate across all levels. This result may be genuine—for
5 example, the time pressure on the task could be felt as a kind of physical demand, for
6 example causing participants to tense up—but it could also suggest the presence of
7 experimenter demand effects. One way to address this in future would be to modify the
8 language used in the offers – rather than referring to difficulty levels, it may be preferable for
9 the offers to refer to the switching rate explicitly instead (alternatively, abstract shapes or
10 colours could be used to label each effort level, avoiding words entirely). That said, we also
11 found that in post-hoc tests the only nonsignificant difference was on the performance
12 subscale, between the two highest effort levels, which directly matches the behavioural result
13 discussed above, that participants performed slightly faster at 80% than 60% effort. That
14 participants were sensitive to this detail gives some reassurance that the Subjective Task
15 Load results were accurate appraisals after all.

16
17 The remainder of our analyses were exploratory in nature and aimed principally at
18 demonstrating how this task can be used for individual differences research. The most
19 parsimonious model according to WAIC included linear and quadratic effects of reward and a
20 linear effect of effort, all of which varied across participants. However, we should be clear
21 that this model is linear on a log-odds scale only, implying non-linear (specifically convex)
22 effort costs on the outcome scale, consistent with other work (see Ritz et al., 2021). The
23 model also indicated there was substantial variability in effort sensitivity across participants,
24 which will be beneficial for individual differences research.

1 In a planned analysis, we used SEM to measure the association between several trait
2 measures and the participant-level parameters from the behavioural model. The only
3 significant association was between Need for Cognition, a construct representing
4 participants' enjoyment of cognitively demanding activity, and reward sensitivity, the extent
5 to which participants' choices changed in line with the offered reward. Possibly this is
6 because participants who score higher on Need for Cognition pay more attention to the
7 parameters of the task. While the lack of other associations, particularly with effort
8 sensitivity, was somewhat surprising, one issue may be overlap between the multiple
9 questionnaire measures we included. Ideally this would have been fully accounted for by the
10 factor analysis, but nevertheless we still saw remaining covariance between the latent factors
11 in the SEM. As we mention in the results section above, this covariance may mean that the
12 factors are making a shared contribution to effort sensitivity which is not detected by the
13 SEM (since the latter only measures the unique contribution of each factor).

14
15 In line with this explanation, when we examined the relationship between each questionnaire
16 and the outcome variables in separate regressions, we found that there were indeed
17 significant associations between effort sensitivity and a number of the mental health related
18 questionnaires (Cognitive Complaints Inventory, Fatigue Severity Scale and Zung
19 Depression Scale). In addition the negative association with Need for Cognition, meaning
20 that participants who enjoy cognitive demanding activity were less sensitive to effort,
21 provides particular reassurance about the external validity of the model. We nevertheless urge
22 caution about not overinterpreting the results of the simple regressions alone; with many tests
23 carried out we unavoidably run into the problem of multiple comparisons, so these results
24 should only be regarded as exploratory for now.

25

1 Finally, we are optimistic about the use of the NST in clinical populations, but again more
2 validation will clearly be needed to support this. In addition, further work could be conducted
3 to design more sophisticated models; those presented in this paper represent a starting point,
4 and natural extensions are to explicitly model the correlations between the sensitivity
5 parameters, or add a lapse component that acknowledges that on some trials participants may
6 simply decide at random. Numerous other model variations can be devised and built, and
7 would be interesting topics of study.

8
9 In summary, we have presented a new task measuring cognitive effort, which resolves a
10 longstanding problem of conflating the effort demanded by a task with its difficulty. Not only
11 have we been able to manipulate effort without changing the difficulty of the task, but we can
12 additionally standardise the difficulty across participants by tailoring the time allowed
13 according to performance at an individual level. This is the first cognitive effort task in which
14 such standardisation can be achieved and means individual differences research can be
15 carried out without concerns around confounding from difficulty or ability.

Questionnaires

NASA Task Load Index. The NASA Task Load Index (Hart & Staveland, 1988), referred to in the main text as the ‘Subjective Task Load’, assesses subjective workload on six subscales: mental demand, physical demand, temporal demand, performance, effort and frustration. For each subscale and, in our case, for each level of effort, participants were asked to rate their experience of the task on a 21-point scale from ‘very low’ to ‘very high’. The six subscales were presented in the same order as above, within which the questions about the different effort levels were randomised. We report participants’ scores on each subscale for each effort level separately.

Cognitive Complaints Inventory. The Cognitive Complaints Inventory (Iverson & Lam, 2013) is a six-item questionnaire in which participants rate their problems with concentration, memory and thinking skills, on a four-point scale from 0 (not at all) to 3 (very much). We report total scores (where higher scores indicate more cognitive complaints).

We appended a catch question (“Select ‘very much’ for this question”) to this questionnaire to identify participants who were not paying attention. We placed this at the end to avoid interfering with the psychometric properties of the questionnaire itself.

Fatigue Severity Scale. The Fatigue Severity Scale (Krupp, LaRocca, Muir-Nash & Steinberg, 1989) is a nine-item questionnaire in which participants rate their experience of

fatigue and the impact fatigue has on their daily activities, on a scale from 1 to 7. We report total scores (where higher scores indicate more fatigue).

International Physical Activity Questionnaire Short Form. The International Physical

Activity Questionnaire Short Form (IPAQ-SF; Lee, Macfarlane, Lam & Stewart, 2011) is a

seven-item scale that measures self-assessed physical activity over the previous seven days.

Participants are asked on how many days and on average for how long each day they spent

engaged in vigorous activity, moderate activity, walking and sitting. These estimates are

weighted by their estimated metabolic requirements and summed to generate an overall score

(termed ‘MET-minutes’, a way of expressing activity relative to a resting metabolic rate), as

follows:

- If necessary, bouts of activity are truncated at a maximum of three hours.
- Walking MET-minutes per week = $3.3 * \text{walking minutes} * \text{walking days}$
- Moderate MET-minutes per week = $4 * \text{walking minutes} * \text{walking days}$
- Vigorous MET-minutes per week = $8 * \text{walking minutes} * \text{walking days}$
- Total MET-minutes per week = Walking Met-minutes + Moderate Met-minutes + Vigorous Met-minutes

Need for Cognition Scale (6-item version). The six-item Need for Cognition Scale (Coelho,

Hanel & Wolf, 2018) measures the extent to which participants enjoy engaging in difficult

cognitive activity. Participants rate each of six statements from 1 (not characteristic of

themselves) to 5 (characteristic). We report participants’ total scores (where higher scores

indicate greater enjoyment of cognitively demanding activity).

We added another catch question to the end of this questionnaire.

Temporal Experience of Pleasure Scale. The Temporal Experience of Pleasure Scale (TEPS; Gard, Gard, Kling & John, 2006) is an 18-item scale with two subscales: a 10-item anticipatory pleasure scale and an 8-item consummatory scale. Each item consists of a statement (e.g. “The smell of freshly cut grass is enjoyable to me”) which participants rate on a 6-point scale from ‘very false for me’ to ‘very true for me’. We report total scores (where higher scores indicate greater disposition to experience of pleasure or, equivalently, lower anhedonia).

Zung Depression Scale. The Zung Depression Scale (Zung, 1965) is a 20-item questionnaire in which participants respond to a series of statements about how they might feel on a 4-point scale from ‘a little of the time’ to ‘most of the time’. We report total scores (where higher scores indicate more depressive symptoms).

Computational Models

Full specification of models

Model 1. Varying Intercept

Equation S1

$$Y_{subject,trial} \sim \text{Bernoulli}(p_{subject})$$

$$p_{subject} = \text{logistic}(\alpha_{subject})$$

$$\alpha_{subject} \sim \text{Normal}(\mu_{\alpha}, \sigma_{\alpha})$$

$$\mu_{\alpha} \sim \text{Normal}(0, 1.5)$$

$$\sigma_{\alpha} \sim \text{Exponential}(2)$$

Model 2. Fixed Intercept and Fixed Linear Effects of Reward and Effort

Equation S2

$$Y_{subject,trial} \sim \text{Bernoulli}(p_{trial})$$

$$p_{trial} = \text{logistic}(\alpha + \beta_{reward}reward_{trial} + \beta_{effort}effort_{trial})$$

$$\alpha \sim \text{Normal}(0, 1.5)$$

$$\beta_{reward} \sim \text{Normal}(0, 1)$$

$$\beta_{effort} \sim \text{Normal}(0, 1)$$

Model 3. Varying Intercept and Fixed Linear Effects of Reward and Effort

Equation S3

$$Y_{subject,trial} \sim \text{Bernoulli}(p_{subject,trial})$$

$$p_{subject,trial} = \text{logistic}(\alpha_{subject} + \beta_{reward}reward_{trial} + \beta_{effort}effort_{trial})$$

$$\alpha_{subject} \sim \text{Normal}(\mu_{\alpha}, \sigma_{\alpha})$$

$$\mu_{\alpha} \sim \text{Normal}(0, 1.5)$$

$$\sigma_{\alpha} \sim \text{Exponential}(2)$$

$$\beta_{reward} \sim \text{Normal}(0, 1)$$

$$\beta_{effort} \sim \text{Normal}(0, 1)$$

Model 4. Varying Intercept and Varying Linear Effects of Reward and Effort

Equation S4

$$Y_{subject,trial} \sim \text{Bernoulli}(p_{subject,trial})$$

$$p_{subject,trial} = \text{logistic}(\alpha_{subject} + \beta_{reward,subject}reward_{trial} + \beta_{effort,subject}effort_{trial})$$

$$\alpha_{subject} \sim \text{Normal}(\mu_{\alpha}, \sigma_{\alpha})$$

$$\mu_{\alpha} \sim \text{Normal}(0, 1.5)$$

$$\sigma_{\alpha} \sim \text{Exponential}(2)$$

$$\beta_{\text{reward,subject}} \sim \text{Normal}(\mu_{\text{reward}}, \sigma_{\text{reward}})$$

$$\mu_{\text{reward}} \sim \text{Normal}(0,1)$$

$$\sigma_{\text{reward}} \sim \text{Exponential}(2)$$

$$\beta_{\text{effort,subject}} \sim \text{Normal}(\mu_{\text{effort}}, \sigma_{\text{effort}})$$

$$\mu_{\text{effort}} \sim \text{Normal}(0,1)$$

$$\sigma_{\text{effort}} \sim \text{Exponential}(2)$$

Model 5. Fixed Intercept, Fixed Linear Effect of Reward and Fixed Linear and Quadratic

Effects of Effort

Equation S5

$$Y_{\text{subject,trial}} \sim \text{Bernoulli}(p_{\text{trial}})$$

$$p_{\text{trial}} = \text{logistic}(\alpha + \beta_{\text{reward}} \text{reward}_{\text{trial}} + \beta_{\text{effort}} \text{effort}_{\text{trial}}$$

$$+ \beta_{\text{quad_effort}} \text{effort}_{\text{trial}}^2)$$

$$\alpha \sim \text{Normal}(0, 1.5)$$

$$\beta_{\text{reward}} \sim \text{Normal}(0, 1)$$

$$\beta_{\text{effort}} \sim \text{Normal}(0, 1)$$

$$\beta_{\text{quad_effort}} \sim \text{Normal}(0, 1)$$

Model 6. Varying Intercept, Fixed Linear Effect of Reward and Fixed Linear and Quadratic

Effects of Effort

Equation S6

$$Y_{subject,trial} \sim \text{Bernoulli}(p_{subject,trial})$$

$$p_{subject,trial} = \text{logistic}(\alpha_{subject} + \beta_{reward}reward_{trial} + \beta_{effort}effort_{trial} + \beta_{quad_effort}effort_{trial}^2)$$

$$\alpha_{subject} \sim \text{Normal}(\mu_{\alpha}, \sigma_{\alpha})$$

$$\mu_{\alpha} \sim \text{Normal}(0, 1.5)$$

$$\sigma_{\alpha} \sim \text{Exponential}(2)$$

$$\beta_{reward} \sim \text{Normal}(0, 1)$$

$$\beta_{effort} \sim \text{Normal}(0, 1)$$

$$\beta_{quad_effort} \sim \text{Normal}(0, 1)$$

Model 7. Varying Intercept, Varying Linear Effect of Reward and Varying Linear and

Quadratic Effects of Effort

Equation S7

$$Y_{subject,trial} \sim \text{Bernoulli}(p_{subject,trial})$$

$$p_{subject,trial} = \text{logistic}(\alpha_{subject} + \beta_{reward,subject}reward_{trial} + \beta_{effort,subject}effort_{trial} + \beta_{quad_effort,subject}effort_{trial}^2)$$

$$\alpha_{subject} \sim \text{Normal}(\mu_{\alpha}, \sigma_{\alpha})$$

$$\mu_{\alpha} \sim \text{Normal}(0, 1.5)$$

$$\sigma_{\alpha} \sim \text{Exponential}(2)$$

$$\beta_{reward,subject} \sim \text{Normal}(\mu_{reward}, \sigma_{reward})$$

$$\mu_{reward} \sim \text{Normal}(0, 1)$$

$$\sigma_{\text{reward}} \sim \text{Exponential}(2)$$

$$\beta_{\text{effort,subject}} \sim \text{Normal}(\mu_{\text{effort}}, \sigma_{\text{effort}})$$

$$\mu_{\text{effort}} \sim \text{Normal}(0,1)$$

$$\sigma_{\text{effort}} \sim \text{Exponential}(2)$$

$$\beta_{\text{quad_effort,subject}} \sim \text{Normal}(\mu_{\text{quad_effort}}, \sigma_{\text{quad_effort}})$$

$$\mu_{\text{quad_effort}} \sim \text{Normal}(0,1)$$

$$\sigma_{\text{quad_effort}} \sim \text{Exponential}(2)$$

Model 8. Varying Intercept, Varying Linear Effect of Reward and Varying Quadratic Effect of Effort

Equation S8

$$Y_{\text{subject,trial}} \sim \text{Bernoulli}(p_{\text{subject,trial}})$$

$$p_{\text{subject,trial}} = \text{logistic}(\alpha_{\text{subject}} + \beta_{\text{reward,subject}} \text{reward}_{\text{trial}} + \beta_{\text{quad_effort,subject}} \text{effort}_{\text{trial}}^2)$$

$$\alpha_{\text{subject}} \sim \text{Normal}(\mu_{\alpha}, \sigma_{\alpha})$$

$$\mu_{\alpha} \sim \text{Normal}(0, 1.5)$$

$$\sigma_{\alpha} \sim \text{Exponential}(2)$$

$$\beta_{\text{reward,subject}} \sim \text{Normal}(\mu_{\text{reward}}, \sigma_{\text{reward}})$$

$$\mu_{\text{reward}} \sim \text{Normal}(0,1)$$

$$\sigma_{\text{reward}} \sim \text{Exponential}(2)$$

$$\beta_{\text{effort}^2,\text{subject}} \sim \text{Normal}(\mu_{\text{effort}^2}, \sigma_{\text{effort}^2})$$

$$\mu_{\text{effort}^2} \sim \text{Normal}(0,1)$$

$$\sigma_{\text{effort}^2} \sim \text{Exponential}(2)$$

Model 9. Varying Intercept, Varying Linear and Quadratic Effects of Reward and Varying

Linear Effect of Effort

Equation S9

$$Y_{subject,trial} \sim \text{Bernoulli}(p_{subject,trial})$$

$$p_{subject,trial} = \text{logistic}(\alpha_{subject} + \beta_{reward,subject}reward_{trial} + \beta_{quad_reward,subject}reward_{trial}^2 + \beta_{effort,subject}effort_{trial})$$

$$\alpha_{subject} \sim \text{Normal}(\mu_{\alpha}, \sigma_{\alpha})$$

$$\mu_{\alpha} \sim \text{Normal}(0, 1.5)$$

$$\sigma_{\alpha} \sim \text{Exponential}(2)$$

$$\beta_{reward,subject} \sim \text{Normal}(\mu_{reward}, \sigma_{reward})$$

$$\mu_{reward} \sim \text{Normal}(0, 1)$$

$$\sigma_{reward} \sim \text{Exponential}(2)$$

$$\beta_{quad_reward,subject} \sim \text{Normal}(\mu_{quad_reward}, \sigma_{quad_reward})$$

$$\mu_{quad_reward} \sim \text{Normal}(0, 1)$$

$$\sigma_{quad_reward} \sim \text{Exponential}(2)$$

$$\beta_{effort,subject} \sim \text{Normal}(\mu_{effort}, \sigma_{effort})$$

$$\mu_{effort} \sim \text{Normal}(0, 1)$$

$$\sigma_{effort} \sim \text{Exponential}(2)$$

Model 10. Varying Intercept, Varying Quadratic Effect of Reward and Varying Linear Effect

of Effort

Equation S10

$$Y_{subject,trial} \sim \text{Bernoulli}(p_{subject,trial})$$

$$p_{subject,trial} = \text{logistic}(\alpha_{subject} + \beta_{quad_reward,subject}reward_{trial}^2 + \beta_{effort,subject}effort_{trial})$$

$$\alpha_{\text{subject}} \sim \text{Normal}(\mu_{\alpha}, \sigma_{\alpha})$$

$$\mu_{\alpha} \sim \text{Normal}(0, 1.5)$$

$$\sigma_{\alpha} \sim \text{Exponential}(2)$$

$$\beta_{\text{quad_reward,subject}} \sim \text{Normal}(\mu_{\text{quad_reward}}, \sigma_{\text{quad_reward}})$$

$$\mu_{\text{quad_reward}} \sim \text{Normal}(0, 1)$$

$$\sigma_{\text{quad_reward}} \sim \text{Exponential}(2)$$

$$\beta_{\text{effort,subject}} \sim \text{Normal}(\mu_{\text{effort}}, \sigma_{\text{effort}})$$

$$\mu_{\text{effort}} \sim \text{Normal}(0, 1)$$

$$\sigma_{\text{effort}} \sim \text{Exponential}(2)$$

Model 11. Varying Intercept, Varying Linear Effects of Reward and Effort and Varying Quadratic Effects of Reward and Effort

Equation S11

$$Y_{\text{subject,trial}} \sim \text{Bernoulli}(p_{\text{subject,trial}})$$

$$p_{\text{subject,trial}} = \text{logistic}(\alpha_{\text{subject}} + \beta_{\text{reward,subject}} \text{reward}_{\text{trial}} + \beta_{\text{effort,subject}} \text{effort}_{\text{trial}} + \beta_{\text{quad_reward,subject}} \text{reward}_{\text{trial}}^2 + \beta_{\text{quad_effort,subject}} \text{effort}_{\text{trial}}^2)$$

$$\alpha_{\text{subject}} \sim \text{Normal}(\mu_{\alpha}, \sigma_{\alpha})$$

$$\mu_{\alpha} \sim \text{Normal}(0, 1.5)$$

$$\sigma_{\alpha} \sim \text{Exponential}(2)$$

$$\beta_{\text{reward,subject}} \sim \text{Normal}(\mu_{\text{reward}}, \sigma_{\text{reward}})$$

$$\mu_{\text{reward}} \sim \text{Normal}(0, 1)$$

$$\sigma_{\text{reward}} \sim \text{Exponential}(2)$$

$$\beta_{\text{effort,subject}} \sim \text{Normal}(\mu_{\text{effort}}, \sigma_{\text{effort}})$$

$$\mu_{\text{effort}} \sim \text{Normal}(0, 1)$$

$$\sigma_{\text{effort}} \sim \text{Exponential}(2)$$

$$\beta_{quad_reward,subject} \sim Normal(\mu_{quad_reward}, \sigma_{quad_reward})$$

$$\mu_{quad_reward} \sim Normal(0,1)$$

$$\sigma_{quad_reward} \sim Exponential(2)$$

$$\beta_{quad_effort,subject} \sim Normal(\mu_{quad_effort}, \sigma_{quad_effort})$$

$$\mu_{quad_effort} \sim Normal(0,1)$$

$$\sigma_{quad_effort} \sim Exponential(2)$$

Model 12. Varying Intercept, Varying Quadratic Effects of Reward and Effort

Equation S12

$$Y_{subject,trial} \sim Bernoulli(p_{subject,trial})$$

$$p_{subject,trial} = \text{logistic}(\alpha_{subject} + \beta_{quad_reward,subject} \text{reward}_{trial}^2 + \beta_{quad_effort,subject} \text{effort}_{trial}^2)$$

$$\alpha_{subject} \sim Normal(\mu_{\alpha}, \sigma_{\alpha})$$

$$\mu_{\alpha} \sim Normal(0, 1.5)$$

$$\sigma_{\alpha} \sim Exponential(2)$$

$$\beta_{quad_reward,subject} \sim Normal(\mu_{quad_reward}, \sigma_{quad_reward})$$

$$\mu_{quad_reward} \sim Normal(0,1)$$

$$\sigma_{quad_reward} \sim Exponential(2)$$

$$\beta_{quad_effort,subject} \sim Normal(\mu_{effort^2}, \sigma_{effort^2})$$

$$\mu_{quad_effort} \sim Normal(0,1)$$

$$\sigma_{quad_effort} \sim Exponential(2)$$

Prior Predictive Checks

Below are plotted the distributions of all of the parameters used in the eight models, which are expressed and plotted on the logodds scale. Additionally we include plots of the prior predictive distributions for the probability of accepting an offer for an individual subject, $p_{subject}$. These are on the probability scale. Where the plots show simulated, rather than analytical, distributions, these represent 1000 simulations with 100 hypothetical participants in each. In all cases, the shaded distributions are 66%, 95% and 100% quantiles.

Priors for the intercepts:

Shown below are the prior distributions for the two types of intercept parameters, fixed (Figure S1) and varying (Figure S2) intercepts. In both cases we see that the priors chosen represent conservative predictions about the data we would expect to observe. Most importantly, a participant's probability of accepting an offer, $p_{subject}$, is constrained to be between 0 and 1. Within that range however the prior density is distributed fairly uniformly, save that it drops off below about 0.2 and above about 0.8. Overall these priors encode beliefs about participants' average acceptance rates that slightly downweight the likelihood of observing the most extreme values but otherwise are fairly agnostic.

1

Figure S1. Prior predictions for the fixed intercept parameter (featured in models 1 and 5), with distribution $\alpha \sim \text{Normal}(0, 1.5)$.

(a) shows the analytical distribution of the intercept α itself, whilst (b) shows the implied prior predictions for the probability of accepting an offer for an individual subject.

2

3

Figure S2. Prior predictions for the varying intercept parameters (featured in models 2, 3, 4, 6, 7, 8, 9, 10, 11 and 12), with distributions $\mu_\alpha \sim \text{Normal}(0, 1.5)$, $\sigma_\alpha \sim \text{Exponential}(2)$ and $\alpha_{\text{subject}} \sim \text{Normal}(\mu_\alpha, \sigma_\alpha)$. (a) and (b) show the analytical distributions of, respectively, the population level average intercept and the standard deviation of this average; (c) shows the distribution of the (subject level) intercepts themselves; and (d) shows the implied prior predictions for the probability of accepting an offer for an individual subject.

4

5

Priors for the reward/effort effects

Shown below are the prior distributions for the reward/effort sensitivity parameters, for the fixed linear (Figure S3) and varying linear (Figure S4) cases and for the fixed and varying quadratic effort sensitivity parameter (Figure S5).

The most important plot for interpreting these priors is in the bottom right of each box, labelled b (or d in the case of Figure S4). This shows the prior on the effect of the reward/effort manipulation on the probability scale. Specifically, this is the predicted change in a participant's probability of accepting the offer when one of the manipulations is changed by one level. For example, moving from 3 to 6 points (or 6 to 9 points, etc.), while effort is kept constant, or vice versa moving from 80% to 60% effort (or 60% to 40% effort, etc.) while reward is kept constant.

In all cases the priors chosen encode conservative beliefs that the effects, if present, are expected to be approximately in the range 0 – 0.25, within which, because of the rightward skew, smaller effects are considered more likely than larger ones.

1

Figure S3. Prior predictions for the fixed linear reward and effort sensitivity parameters (featured in models 1, 3, 5 and 6), with distribution $\beta \sim \text{Normal}(0, 1)$. (a) shows the analytical distribution of the sensitivity β itself, whilst (b) shows the implied predictions for the change in probability of accepting an offer as the reward or effort changes by one level (e.g. from 3 to 6 points, or 80% to 60% effort etc.)

2

3

4

5

6

1

Figure S4. Prior predictions for the varying linear reward and effort sensitivity parameters (featured in models 4, 7, 8, 9, 10 and 11), with distributions $\mu_\beta \sim \text{Normal}(0,1)$, $\sigma_\beta \sim \text{Exponential}(2)$ and $\beta_{\text{subject}} \sim \text{Normal}(\mu_\beta, \sigma_\beta)$.

(a) and (b) show the analytical distributions of, respectively, the population level average sensitivity and the standard deviation of this average; (c) shows the distribution of the (subject level) sensitivity parameters themselves; and (d) shows the implied predictions for the change in probability of accepting an offer as the reward or effort changes by one level (e.g. from 3 to 6 points, or 80% to 60% effort etc.)

Figure S5. Prior predictions for the quadratic reward/effort sensitivity parameters with distributions $\beta_{\text{quad_effort}} \sim \text{Normal}(0,1)$ (fixed effect in models 5 and 6) and $\mu_{\text{quad_effort}} \sim \text{Normal}(0,1)$, $\sigma_{\text{quad_effort}} \sim \text{Exponential}(2)$ and $\beta_{\text{quad_effort,subject}} \sim \text{Normal}(\mu_{\text{quad_effort}}, \sigma_{\text{quad_effort}})$ (varying effects in models 7, 8, 9, 10, 11 and 12). The distributions of the sensitivity parameters themselves are the same as for the linear parameters plotted above, in Figure S3(a) for the fixed effect, and in Figure S4(a, b and c) for the varying effects. Below we plot the implied predictions for the change in probability of accepting an offer as the required effort changes by one level (e.g. from 80% to 60% effort etc.), for (a) a fixed parameter, and (b) varying

3 Bayesian Modelling

4

Figure S6. Differences in WAIC relative to the best performing model (Model 4). Full plot of all eight models that were considered. This figure is a counterpart to Figure 6 in the main text.

5

6

7

8

Figure S7. *Posterior predictions for Model 9* ($vI + vR + vR^2 + vE$). Plots show mean (black line) and posterior quantiles (95%, 80% and 50%) of the predicted probability of accepting an offer across each level of reward and effort. Note that these are predictions for simulated new participants and therefore incorporate uncertainty not just about the average effect of the manipulations in the population, but also about the behaviour of individual participants.

Structural Equation Modelling

We considered four factor structures:

- One with a distinct latent factor for each questionnaire
- Another in which the all questions mapped onto a single latent factor, equivalent to a ‘P’ factor in psychiatry (Caspi et al., 2013)
- A structure in which they were grouped by broad cognitive domain
- Another in which the questionnaires directly relevant to mental health symptoms were grouped together

These are shown graphically in Figure S8

(a) – (d) below.

We ran confirmatory factor analyses with each of these models and then compared their relative model fits using three metrics – overall log likelihood, Akaike’s Information Criterion and the Bayesian Information Criterion. The results are presented in the Table S4 below. The ‘Full’ structure, with a distinct latent factor for each questionnaire, consistently fitted the data best across all three measures.

Table S4. Results of model comparison for the confirmatory factor analysis.

Factor Structure	Log Likelihood	AIC	BIC
Full structure	-27237	54756	55273
MH symptoms grouped	-27741	55740	56213
Cognitive domain	-27827	55912	56386
'P'-like structure	-28281	56814	57277

1

2

3 Using this winning factor structure, we then constructed a structural equation model to

4 predict our three subject-level parameters from the computational model using the latent

5 factors for the questionnaires, plus the demographics measures (age and level of education).

6 The results are presented in Table S5 below.

7

Sensitivity Analyses

In this section we repeat the modelling analyses using the two runner-up models, named Model 4 ($vI + vR + vE$) and Model 7 ($vI + vR + vE + vE^2$). First, the posterior parameter estimates are shown below in Figures S10 and S11. We can see that the intercept, reward and effort sensitivity parameter estimates are all substantially similar both across Models 4 and 9 and to those in the winning Model 9 ($vI + vR + vR^2 + vE$), shown in Figure 8 in the main text. Of note however is that while Models 4 and 7 had similar WAIC scores, Model 7 is less precise than Model 4 in its estimate of the linear effort sensitivity parameter; at the same time the quadratic effort sensitivity parameter both overlaps with zero and is highly colinear with the linear parameter (the correlation between the two is $r = -0.92, p < .001$). Together this suggests that the linear and quadratic effort terms are redundant and trade off with one another. Nevertheless, focussing on the linear reward and effort sensitivity parameters we see, as with the winning Model 9, that these do not overlap zero, again according with the earlier ANOVA results).

Figure S10. *Posterior distributions of the population-level intercept parameters in models 4 ($vI + vR + vE$) and 7 ($vI + vR + vE + vE^2$). The vertical line indicates the mean of each distribution, and the shaded region the 66% quantile interval.*

Figure S11. *Posterior distributions of the population level reward and effort sensitivity parameters in models 4 ($vI + vR + vE$) and 7 ($vI + vR + vE + vE^2$). The vertical line indicates the mean of each distribution, and the shaded region the 66% quantile interval. The quadratic effort sensitivity parameter (Model 7: $\mu_{\beta, effort^2}$) substantially overlaps 0 and, additionally, there is a very large negative correlation between this and the model 7 linear effort parameter, $r = -0.92$, $p < .001$, indicating substantial collinearity.*

The posterior predictions from Model 4 ($vI + vR + vE$) and Model 7 ($vI + vR + vE + vE^2$) are shown in Figures S12 and S13. Again we see that both models produce very similar predictions, and both produce a reasonable overall fit to the data while still including substantial uncertainty about the behaviour of an individual participant. In this respect the two models are nearly identical to the winning model considered in the main text, Model 9.

Figure S12. *Posterior predictions from Model 4 ($vI + vR + vE$).* Plots show mean (black line) and posterior quantiles (95%, 80% and 50%) of the predicted probability of accepting an offer across each level of reward and effort. Note that these are predictions for simulated new participants and therefore incorporate uncertainty not just about the average effect of the manipulations in the population, but also about the behaviour of individual participants.

1

Figure S13. *Posterior predictions from Model 7* ($vI + vR + vE + vE^2$). Plots show mean (black line) and posterior quantiles (95%, 80% and 50%) of the predicted probability of accepting an offer across each level of reward and effort. Note that these are predictions for simulated new participants and therefore incorporate uncertainty not just about the average effect of the manipulations in the population, but also about the behaviour of individual participants.

2

3

4 Finally, we examined the correlations between the participant-level effort sensitivity

5 parameters (from both Model 4, $vI + vR + vE$, and Model 7, $vI + vR + vE + vE^2$) and the

6 probability of success on the task (see Figure S12). Again mirroring the results with the

7 winning Model 9 ($vI + vR + vR^2 + vE$), these correlations were not significantly different

8 from zero (Model 4: $r(288) = 0.10, p = .09$; Model 7: $r(288) = 0.10, p = .07$), supporting our

9 conclusion that effort sensitivity was not confounded by probability discounting.

10

Overall these sensitivity analyses support the conclusion that all of the three best performing models on WAIC score lead to very similar inferences, and therefore the results reported in the main text using Model 9 ($vI + vR + vR^2 + vE$) are robust.

Figure S14. *Relationship between the probability of success and effort sensitivity.* Plots show (left) Model 4 ($vI + vR + vE$), and (right) Model 7 ($vI + vR + vE + vE^2$). The correlation was non-significant, implying that effort sensitivity is not confounded by probability discounting in this task.

Further tests of correlations between allowed time, success rate and completion time

Table S7. Cognitive Effort Task: Correlations between time allowed, success rate and completion time for each combination of reward and effort.

Correlation between time allowed and success rate		
Reward: Effort	r	t-test
3: 20%	$r = 0.07$	$t(253) = 1.15, p = .25$
3: 40%	$r = 0.14$	$t(245) = 2.20, p = .03^*$
3: 60%	$r = 0.06$	$t(223) = 0.86, p = .39$
3: 80%	$r = 0.05$	$t(253) = 0.72, p = .47$

6: 20%	$r = 0.03$	$t(278) = 0.54, p = .59$
6: 40%	$r = 0.07$	$t(276) = 1.09, p = .28$
6: 60%	$r = 0.06$	$t(266) = 0.83, p = .41$
6: 80%	$r = 0.05$	$t(261) = 0.75, p = .45$
9: 20%	$r = 0.01$	$t(284) = 0.10, p = .92$
9: 40%	$r = 0.14$	$t(283) = 2.30, p = .02^*$
9: 60%	$r = 0.07$	$t(276) = 1.22, p = .22$
9: 80%	$r = -.10$	$t(275) = 1.60, p = .11$
12: 20%	$r = 0.04$	$t(286) = 0.71, p = .48$
12: 40%	$r = 0.04$	$t(286) = 0.61, p = .54$
12: 60%	$r = 0.08$	$t(285) = 1.38, p = .17$
12: 80%	$r = 0.07$	$t(283) = 1.21, p = .23$
Correlation between time allowed and completion time		
Reward: Effort	r	t-test
3: 20%	$r = -.40$	$t(253) = 6.95, p < .001^{***}$
3: 40%	$r = -.48$	$t(245) = 8.55, p < .001^{***}$
3: 60%	$r = -.52$	$t(223) = 9.09, p < .001^{***}$
3: 80%	$r = -.34$	$t(214) = 5.38, p < .001^{***}$
6: 20%	$r = -.42$	$t(278) = 7.69, p < .001^{***}$
6: 40%	$r = -.47$	$t(276) = 8.80, p < .001^{***}$
6: 60%	$r = -.51$	$t(266) = 9.59, p < .001^{***}$
6: 80%	$r = -.51$	$t(261) = 9.69, p < .001^{***}$
9: 20%	$r = -.43$	$t(284) = 7.97, p < .001^{***}$

9: 40%	$r = -.59$	$t(283) = 12.2, p < .001^{***}$
9: 60%	$r = -.55$	$t(276) = 10.9, p < .001^{***}$
9: 80%	$r = -.52$	$t(275) = 10.0, p < .001^{***}$
12: 20%	$r = -.45$	$t(286) = 8.49, p < .001^{***}$
12: 40%	$r = -.52$	$t(286) = 10.4, p < .001^{***}$
12: 60%	$r = -.57$	$t(285) = 11.8, p < .001^{***}$
12: 80%	$r = -.51$	$t(283) = 10.0, p < .001^{***}$
