Keywords: Emotion Regulation, Resting State, Amygdala, preregistration, cortico-limbic connectivity

Abstract

Neuroimaging functional connectivity analyses have shown that the negative coupling between amygdala and cortical regions is linked to better emotion regulation (ER) in experimental task settings. However, less is known about the neural correlates of ER traits or dispositions. The present study aimed to (1) replicate the findings of differential cortico-limbic coupling during resting state depending on the dispositional use of emotion regulation strategies. Furthermore, the study aimed to (2) extend prior findings by examining whether differences in cortico-limbic coupling during resting state predict experiential and neuronal ER success in a standard ER task. To this end, $N=107$ healthy adults completed the Emotion Regulation Questionnaire (ERQ), underwent an 8-min resting-state fMRI acquisition and completed a reappraisal task during fMRI. Functional connectivity maps of basolateral and centromedial amygdala nuclei were estimated with a seed-based approach regarding associations with regions of the prefrontal cortex, and were then correlated with ERQ scores as well as experiential and neuronal ER success. All hypotheses and the analysis plan are preregistered at <https://osf.io/8wsgu>. Opposed to prior findings, we were not able to replicate a correlation of dispositional ER strategy use with functional connectivity between amygdala and PFC regions ($p > 0.05$, FWE-corrected). Furthermore, there was no association of experiential and neuronal reappraisal success with functional connectivity between amygdala and insula as well as PFC ($p > 0.05$, FWE-corrected). The present preregistered study calls into question the reported association between individual

differences in resting state cortico-limbic connectivity and dispositional use of ER strategies. However, ongoing advances in functional brain imaging and distributed network approaches may leverage the identification of reliable functional connectivity patterns that underlie successful emotion regulation.

1 Introduction

Emotion regulation (ER) is defined by the activation of a goal to change an unfolding emotional response and can be described as any process by which individuals modify their emotional experiences, expressions, and physiology (Gross, 1998, 2015). Being able to effectively regulate one's emotional reactions is of crucial importance for appropriate social interactions and an essential feature of mental and physical health (English, John, Srivastava, & Gross, 2012; Gross & Munoz, 1995; Hu et al., 2014; Johnstone & Walter, 2014; Kanske, Heissler, Schönfelder, & Wessa, 2012; Kret & Ploeger, 2015). The influential Process Model of Emotion Regulation and its extension, (Gross, 1998, 2015) categorizes strategies of emotion regulation according to the time point in the emotion generation process, at which they are being implemented. Cognitive change (e.g. reappraisal) appears early in the process (antecedent-focused) and refers to altering the value of the emotion eliciting stimulus, whereas response modulation (e.g. expressive suppression) takes effect later and aims at altering the emotional response. The most studied reappraisal strategy is reinterpretation, which implies changing the meaning of a stimulus (Ochsner, Bunge, Gross, & Gabrieli, 2002). Another reappraisal strategy is detachment (distancing) where one is taking the perspective of an uninvolved observer in order to reduce the subjective relevance of the stimuli (Kalisch et al., 2005; Walter et al., 2009). It has been assumed that cognitive reappraisal (reinterpretation and detachment) as antecedent-focused strategies are most effective because the emotional response has not fully unfolded and the negativity of an event itself is altered, whereas response-focused strategies such as expressive suppression often fail in fully modifying the emotional response since they are initiated later in the emotion-generative process (for a review see Gross, 2002). Nevertheless, people implement both strategies in their daily lives and there are results pointing to expressive suppression being advantageous in some contexts (Bonanno & Burton, 2013; Bonanno, Papa, Lalande, Westphal, & Coifman, 2004), while reappraisal may also turn out unsuccessful (Aldao, Sheppes, & Gross, 2015). Research that investigates the underlying mechanisms influencing these long and short-term outcomes of both strategies is still ongoing.

Until recently, this research has roughly followed two approaches (Tull & Aldao, 2015): A task-related, experimental approach (hereinafter referred to as task-related ER) and an approach investigating individual differences in ER abilities and dispositional use of strategies, respectively (hereinafter referred to as dispositional ER). The task-related approach uses experimental tasks, in which participants are instructed to use one or more ER strategies to decrease or increase (mostly negative) emotions and investigates effects on different emotional (experiential), behavioral and psychophysiological outcomes. The dispositional approach frequently relies on self-report questionnaires to evaluate ER abilities and dispositional use of ER strategies. One of the most widely used self-report measures of reappraisal (with an emphasis on reinterpretation) and expressive suppression is the Emotion Regulation Questionnaire (ERQ, Gross & John, 2003). Based on the Process Model of Emotion Regulation, the ERQ evaluates the dispositional use of these two strategies.

In experimental settings, task-related reappraisal has been shown to be effective in changing emotional experiences, behavior and physiological responses (Webb, Miles, & Sheeran, 2012). The authors report detachment ($d^+ = 0.45$) being significantly more advantageous than reinterpretation ($d^+ = 0.36$). Expressive suppression proved to be effective in the regulation of emotional experiences and behavioral, but not physiological responses (Webb et al., 2012). In

contrast, a recent meta-analysis on psychophysiological outcomes of task-related ER reports mixed findings with low to medium effect-sizes for both reappraisal and expressive suppression and mostly non-significant meta-analytical effects (Zachringer, Jennen-Steinmetz, Schmahl, Ende, & Paret, 2020). With regard to dispositional ER, the dispositional use of reappraisal, measured with the ERQ, has been linked to interpersonal functioning, and psychological as well as physical well-being (Gross & John, 2003). Moreover, Aldao, Nolen-Hoeksema, and Schweizer (2010) could meta-analytically show that dispositional reappraisal is negatively associated with symptoms of psychopathology. In contrast, dispositional suppression was positively associated with psychopathology with medium to large effect sizes (Aldao et al., 2010; Hu et al., 2014), worse interpersonal functioning, and greater risk of depression (Gross & John, 2003). Hence, with regard to emotional experiences, both strategies have shown to be successful in the short-term regulation of emotions, while there are mixed findings about short-term physiological outcomes. Reappraisal is advantageous with regard to long-term (self-reported) psychological outcomes.

Neuroscientific studies of healthy but also impaired ER are able to contribute to the understanding of the mechanisms and underlying processes leading to these outcomes. Mostly, this research is investigating neuronal activity in brain regions implicated in cognitive control (i.e. the prefrontal cortex, PFC) and brain regions implicated in emotional processing (i.e. amygdala and insula) as well as the coupling between these structures. Functional brain imaging studies repeatedly showed that activation in the PFC (i.e. the anterior cingulate cortex (ACC), medial (m)PFC, and dorsolateral (dl) PFC) and reduction of amygdala activation is associated with detachment in ER tasks (Dörfel et al., 2014; Erk, von Kalckreuth, & Walter, 2010; Kalisch et al., 2005; Koenigsberg et al., 2010; Ochsner, Silvers, & Buhle, 2012; Schardt et al., 2010; Walter et al., 2009). During expressive suppression, activity within similar PFC regions, and the supplementary motor area (SMA) has been reported (Dörfel et al., 2014; Phillips, Ladouceur, & Drevets, 2008; Vrticka, Sander, & Vuilleumier, 2011). In contrast, suppression has been associated with significant increases in amygdala and insula activity (Dörfel et al., 2014; Goldin, McRae, Ramel, & Gross, 2008; Hayes et al., 2010; Vanderhasselt, Kuhn, & De Raedt, 2013). It can therefore be assumed that the interaction between PFC regions and regions of emotional processing is different for the two strategies.

For successful ER, it is assumed that dorsal PFC regions exert an inhibitory effect on regions of emotional processing via ventral PFC regions (Buhle et al., 2014; Lee, Heller, van Reekum, Nelson, & Davidson, 2012; Ochsner et al., 2002; Wager, Davidson, Hughes, Lindquist, & Ochsner, 2008). Consequently, in reappraisal tasks, task-related functional connectivity has been reported between the amygdala and the PFC (Banks, Eddy, Angstadt, Nathan, & Phan, 2007; Erk, Mikschl, et al., 2010; Paschke et al., 2016; Schardt et al., 2010; Sripada et al., 2014; Winecoff, Labar, Madden, Cabeza, & Huettel, 2011). Moreover, functional coupling of the amygdala with ventral and dorsal PFC regions was significantly correlated to experiential (self-reported) emotion regulation success (Banks et al., 2007; Paschke et al., 2016). Lee et al. (2012) suggested that functional coupling between the amygdala and prefrontal regions as well as pregenual ACC during cognitive reappraisal depends on individual differences in the capacity for reducing negative emotion. In line with this, studies including patients with psychological disorders with reduced ability to regulate emotions (e.g. depression and anxiety) have found deficits in functional and effective connectivity between the amygdala and frontal brain regions (Clauss et al., 2014; Cullen et al., 2011; Erk, Mikschl, et al., 2010; Mochcovitch, da Rocha Freire, Garcia, & Nardi, 2014; Niedtfeld et al., 2012; Pico-Perez, Radua, Steward, Menchon, & Soriano-Mas, 2017; Radaelli et al., 2015). Additionally, there is evidence that not only task-related connectivity but also alterations in resting-state functional connectivity of (among others) PFC, amygdala and insula are associated with depression and anxiety (Barch, 2017; Menon, 2011; Zhang et al., 2014). Resting-state functional brain connectivity (rsFC) reflects

intrinsic connectivity, that is correlated temporal patterns among brain regions during rest. The resting-state networks closely match networks that have been continuously reported by different task conditions pointing to an intrinsic functional brain architecture important for task-specific brain activation (Smith et al., 2009). This also applies to ER related brain networks (i.e. default mode network, the executive control network and the salience network, see Beckmann, DeLuca, Devlin, & Smith, 2005; Damoiseaux et al., 2006; Seeley et al., 2007). Hence, it can be suggested that activity in task-related ER networks and resting-state connectivity between PFC and the amygdala show associations.

Gabard-Durnam et al. (2016) propose that experiences of stimulus-elicited coactivations in ER brain regions form these resting-state connectivity patterns (long-term phasic molding hypothesis), particularly during development in childhood and adolescence. The authors found that in a sample of children and adolescents, stimulus-elicited amygdala-mPFC connectivity predicted rsFC two years later. It is likely that the dispositional, daily use of a specific ER strategy and the experience of (un)successful ER alters the functional architecture of these brain networks, which is represented in rsFC. In turn, it can be assumed that functional connectivity influences dispositional, daily strategy choice as well as strategy implementation.

Successful task-related ER (defined by a decrease in self-reported emotional experiences as well as a deactivation of brain regions engaged in emotion processing) as well as dispositional ER should therefore be associated with rsFC between amygdala and PFC. However, few studies so far have directly investigated this. Picó-Pérez et al. (2018) found rsFC between the amygdala and PFC regions as well as the insula to be distinctly associated with dispositional use of suppression and reappraisal, respectively, as measured by the ERQ (Gross & John, 2003). In contrast, Uchida et al. (2015) could not find associations with self-reported dispositional ER (measured with the Difficulties in Emotion Regulation Scale, DERS, Gratz & Roemer, 2004). In a study by Morawetz et al. (2016), task-related ER (reinterpretation) success, defined by affect ratings, was positively correlated with rsFC between the right amygdala and the left ventrolateral (vl)PFC as well as the insula. Uchida et al. (2015) demonstrated that greater reappraisal (reinterpretation) success, again measured by affect ratings, showed a significant negative correlation with rsFC of the right amygdala with mPFC. However, the two latter studies only focused on experiential ER success (affect ratings), and did not report results on neuronal ER success (defined by deactivations in regions of emotional processing). Additionally, to our knowledge, findings of these few existing studies have not been validated by replications.

Following this, the present study aimed at replicating and extending findings of associations between ER and rsFC of amygdala and PFC. To define the replication attempts, we draw upon the definitions proposed by Zwaan, Etz, Lucas, and Donnellan (2018), who differentiate between direct and conceptual replication studies. A direct replication is described as a study that attempts to recreate the critical elements (e.g., samples, procedures, and measures) of an original study. The authors underline that, “a direct replication does not have to duplicate all aspects of an original study. Rather it must only duplicate those elements that are believed necessary for producing the original effect.” A conceptual replication is defined as a study with theoretically meaningful changes “to the original procedures that might make a difference with regard to the observed effect size” (p. 3).

The present study specifically pursued three objectives: 1) We aimed at an investigation whether individual differences in *dispositional reappraisal and expressive suppression* (defined by self-reported habitual use as measured with the ERQ) can explain variance in rsFC between amygdala and PFC. To do so, we reanalyzed own existing data (Diers, Weber, Brocke, Strobel, & Schonfeld, 2014; Scheffel et al., 2019) from three related ER experiments containing

measures of dispositional use of reappraisal and suppression (via ERQ) and fMRI resting state scans in order to replicate the findings by Picó-Pérez et al. (2018). We aimed at a direct replication according to the definition outlined above. Due to using existing data there were methodological differences between our investigation and the Picó-Pérez study which will be outlined in the methods section and in supplementary table S23. However, these differences are mostly technical in nature, and do not lead to a different operationalization of the constructs.

2) We aimed at investigating whether individual differences in task-related, *experiential reappraisal success* (as defined by a decrease in self-reported arousal during a reappraisal task) explains variance in rsFC between the amygdala and PFC. To this end, we reanalyzed existing data from the aforementioned experiments, which focused on detachment as a reappraisal strategy. This investigation is inspired by the study of Uchida et al. (2015). Because there are important differences with regard to the operationalization of the constructs and the experimental procedure between our study and the Uchida study (see supplementary table S24), the current investigation can be a conceptual replication at best.

3) Extending the findings of Uchida et al. (2015), we aimed at an investigation of associations between task-related, *neuronal reappraisal success* (as defined by a decrease of amygdala activity during emotion regulation) and rsFC between the amygdala and PFC, again using existing data of the aforementioned data sets.

Replication attempt and extension of existing studies on rsFC and dispositional as well as task-related emotion regulation success

Picó-Pérez et al. (2018) reported that dispositional reappraisal was negatively correlated with rsFC between left basolateral amygdala and left insula as well as dACC, and between right basolateral amygdala and SMA/dACC as well as left insula. For dispositional suppression, a positive correlation was found with rsFC between right basolateral amygdala and dACC, a negative correlation with rsFC between left centromedial amygdala and SMA. The study was conducted with 48 healthy participants (23 females) with a mean age of 39.7 years. Participants filled out the Spanish version of the ERQ and underwent a resting fMRI scan. Detailed methods in comparison to our replication attempts can be found in Supplementary Table S23.

Uchida et al. (2015) report a significant negative correlation of task-related experiential reappraisal success with rsFC between the right amygdala and mPFC. This study investigated 62 participants (32 females, mean age 22.3 years), reflecting a broad range of ER ability due to preselection according to DERS scores (Gratz & Roemer, 2004). The participants underwent an fMRI reappraisal task, where they were instructed to either attend to neutral or negative pictures or reinterpret the pictures in order to reduce their negative feelings (reinterpretation as reappraisal strategy). At the end of each trial, participants rated their negative emotional reaction (affect rating). Reappraisal success (reappraisal score) was defined as the difference between the affect rating for the Attend Negative condition minus the Reappraise Negative condition during scanning. Additionally, the participants underwent a resting fMRI scan. The authors did not report associations between rsFC and the fMRI responses during the reappraisal task (neuronal emotion regulation success). Detailed methods in comparison with our replication attempt can be found in Supplementary Table S24

Based on the two studies described above, we developed the following hypotheses: Regarding aim 1, we took into account the connectivity results of Picó-Pérez et al. (2018) with and without global signal regression (GSR) and hypothesized that there is a significant negative correlation of *dispositional reappraisal use* with rsFC between 1a) left basolateral amygdala and left insula, 1b) left basolateral amygdala and dACC, 1c) right basolateral amygdala and left insula, 1d)

right basolateral amygdala and the SMA/dACC. Additionally, we hypothesized that there is a negative correlation of *dispositional suppression use* with rsFC between 1e) left centromedial amygdala and the SMA, 1f) right basolateral amygdala and dACC. With respect to aim 2, we took into account the results of both, Picó-Pérez et al. (2018) and Uchida et al. (2015), and hypothesized that there is a negative correlation of task-related *experiential reappraisal success* with rsFC between 2a) left amygdala and left insula, 2b) right amygdala and left insula, 2c) the amygdala and dorsomedial (dm) PFC, 2d) amygdala and ventromedial PFC, and 2e) a correlation of *experiential reappraisal success* with rsFC between the amygdala and dlPFC. Lastly, we hypothesized that there is a correlation between task-related *neuronal reappraisal success* with rsFC between 3a) the amygdala and insula, 3b) amygdala and dmPFC, and 3c) amygdala and dlPFC. Hypotheses, methods and analysis plan were preregistered and can be found at <https://osf.io/8wsgu>.

2 Methods

This study is a reanalysis of data collected within a larger project on neural correlates and individual differences of ER and its aftereffects (SFB 940 Project A5). To achieve a reliable sample size, we combined three samples from three slightly different ER experiments. Please note that results regarding research questions on task related effects as well as associations with genetic polymorphisms are published elsewhere (Diers et al., in preparation; Gärtner et al., 2019; Scheffel et al., 2019). Results on the research question of this publication have not been reported in any of these publications. We report how we determined our sample size, all data exclusions (if any), all manipulations, and all measures in the study (Simmons, Nelson, & Simonsohn, 2012). The study was preregistered at <https://osf.io/8wsgu>. The datasets, scripts and analysis routines can be found at <https://osf.io/p7hb5/>. Due to the analysis of existing data, our procedures deviated from the methodological procedures of the original studies, differences can be found in detail in Supplementary Tables S23 and S24.

2.1 Participants

Sample size calculation was based on feasibility considerations. This resulted in a target sample size of over 48 participants per experiment. At the end of the data collection, 136 healthy participants took part in the study, $N = 42$ in experiment 1, $N = 47$ each in experiment 2 and 3. Participants were mostly students from the local university community. All participants were right-handed, pre-screened for magnetic resonance imaging (MRI) contraindications (e.g., metal plates or implants), and had no current or prior medical, neurological or psychiatric illness or treatment. The experimental protocol was approved by the ethics committee of the TU Dresden (EK 10012012). Participation was voluntary and written consent was obtained. Participants received financial compensation for their time and effort.

After inspection of the data, $N = 29$ had to be excluded because of missing resting state sessions or due to missing of significant parts of the amygdala in resting state images. Data of $N = 107$ participants (64 female; age: 24.4 ± 4.2 years, range: 18-48) were analyzed ($N = 27$ in experiment 1, $N = 40$ in experiment 2 and 3, respectively). Please note that the sample size of some calculations is smaller due to missing questionnaire data or task related fMRI data (see Table 1 below). Given our sample size, a power analysis with G*Power (Faul, Erdfelder, Buchner, & Lang, 2009) indicated that for correlational analyses, we were able to detect an r of .31 with a power of .80 (two-tailed, $\alpha = 0.05/4$ corrected for multiple comparisons for analyses on four amygdala nuclei).

Table 1. Sample characteristics and descriptive results of dispositional emotion regulation.

	<i>N</i>	<i>M</i> ($\pm$ <i>SD</i>)
Age	106	24.4 ($\pm$ 4.2)
Gender (male/female)	106	42/64
ERQ reappraisal ($\alpha = 0.74$)	101	4.8 ($\pm$ 0.8)
ERQ suppression ($\alpha = 0.76$)	102	3.4 ($\pm$ 1.2)

Note. α = Cronbach's Alpha; differences in *N* are due to missing demographic or questionnaire data of single participants

2.2 Study procedure

All three experiments contained two sessions one week apart from each other. In the first session, a functional MRI (fMRI) measurement during an experimental emotion regulation task (ERT), self-reported arousal ratings (AR) after each experimental run, a structural MRI (sMRI) measurement and a stimuli re-exposure fMRI run were performed. In the second session a resting state fMRI (RS-fMRI) and another stimuli re-exposure fMRI run was completed. Additionally, the participants filled in questionnaires measuring individual differences on several traits and abilities (see 2.3). Please refer to Supplementary Figure S1 for a detailed description of the experimental procedure.

2.3 Emotion regulation (ER) task and experiential reappraisal success

Participants performed an ER task with negative (categories: animal, body, disaster, disgust, injury, suffering, violence, and weapons) and neutral (categories: objects, persons, and scenes) pictures. Pictures were taken from the International Affective Picture System (IAPS, Lang, Bradley, & Cuthbert, 2008) and the Emotional Picture Set (EmoPicS, Wessa et al., 2010). Pictures were divided into subsets and randomly assigned to conditions. Valence (*V*) and arousal (*A*) were comparable between the experiments: For negative pictures, values were *V* = 2.67-2.81 and *A* = 5.54-5.74 (experiment 1), *V* = 2.65-2.71 and *A* = 5.69-5.85 (experiment 2), and *V* = 2.65-2.71 and *A* = 5.55-5.85 (experiment 3). For neutral pictures, values were *V* = 4.98-5.16 and *A* = 2.86-3.04 (experiment 1), *V* = 5.13-5.17 and *A* = 2.94-2.96 (experiment 2), and *V* = 5.13-5.19 and *A* = 2.85-2.96 (experiment 3).

The ER tasks differed slightly across the three experiments. However, all had in common that participants went through a Permit and a Detach condition (Diers et al., in preparation; Diers et al., 2014; Gärtner et al., 2019; Scheffel et al., 2019). During the Permit condition, participants should take a close look at the pictures and permit any emotions, that might arise. During the Detach condition, they were asked to "take the position of a non-involved observer, thinking about the picture in a neutral way." Strategies were trained outside the MRI scanner.

Each experimental trial consisted of a stimulation period and a relaxation period. In the stimulation period, a picture was presented for 8 (experiment 1 and 3), or 10 seconds (experiment 2). Within the initial 2 s of this period, a semi-transparent overlay containing the instruction was presented in the center of the picture. Afterwards, a fixation cross was presented (relaxation period). After each trial (experiment 1) or block (experiment 2 and 3), participants rated their emotional arousal. The difference between arousal ratings for the conditions Negative Permit and Negative Detach was determined as *experiential reappraisal success*.

After the ER experiment, participants were asked whether they followed the instructed strategies. All participants stated that they did so. For a more detailed description of the three experiments, please see Supplementary Methods.

2.4 Psychometric measurements (dispositional emotion regulation and affect)

Participants completed several questionnaires on personality traits, ER abilities, need for cognition, thought suppression, mindfulness, acceptance, worry, and anxiety (for a complete list of measures, see <https://osf.io/8wsgu>). The following questionnaires were used in the present study: The German version of the Emotion Regulation Questionnaire (ERQ, Gross & John, 2003; German version: Abler & Kessler, 2009) to determine *dispositional reappraisal and suppression use*, and the Positive and Negative Affect Schedule (PANAS, Watson, Clark, & Tellegen, 1988; German version: Janke & Glöckner-Rist, 2014) to determine positive and negative affect.

2.5 MRI data acquisition

Functional and structural imaging was performed on a 3.0 Tesla Siemens Magnetom Trio scanner (Siemens AG, Erlangen, Germany), using a 12-channel head coil. Functional data were obtained using a T2*-weighted echo-planar imaging sequence. The field of view (FOV) had a size of $192 \times 192 \text{ mm}^2$ with a matrix size of 64×64 , flip angle 80° , slice gap 1 mm, repetition time (TR) = 2410 ms, and echo time (TE) = 25 ms. Forty-two axial slices were acquired with a voxel size of $3.0 \times 3.0 \times 2.0 \text{ mm}^3$. Stimuli were presented using Presentation (Neurobehavioral Systems, Albany, CA, USA). For each subject, anatomical (T1-weighted) images were acquired using an MPRAGE sequence consisting of 176 sagittal slices with a thickness of 1 mm (TR: 1900 ms, TE: 2.26 ms, flip angle 9° , FOV: $256 \times 256 \text{ mm}^2$, matrix size 256×256 , voxel size: $1 \times 1 \times 1 \text{ mm}^3$) (Diers et al., 2014; Gärtner et al., 2019; Scheffel et al., 2019).

2.6 Data analysis

2.6.1 Resting state functional connectivity

2.6.1.1 Seed and ROI definition

The selection of the seed regions was based on Picó-Pérez et al. (2018) and corresponded to left basolateral amygdala (BLA), right BLA, left centromedial amygdala (CMA), and right CMA for the resting-state analyses (see Figure 1A). For all four nuclei, maximum probability maps were created using the SPM Anatomy toolbox v.2.2c (Eickhoff et al., 2005). The probability threshold was set to 40% for each voxel to provide a sufficient areal coverage of the anatomical structure (Baur, Hanggi, Langer, & Jancke, 2013; Eickhoff, Heim, Zilles, & Amunts, 2006). Note that in accordance with Picó-Pérez et al. (2018), the CMA comprised centromedial and superficial divisions of left and right amygdala.

The ROI mask for the PFC was restricted to a 56,833-voxel mask ($2 \times 2 \times 2 \text{ mm}^3$; see Figure 1B) created with the Wake Forest University (WFU) Pick-atlas toolbox (Maldjian, Laurienti, Kraft, & Burdette, 2003). Following the procedure described by Picó-Pérez et al. (2018), the mask comprised different regions of the frontal lobe (i.e., inferior frontal, middle frontal, superior frontal, medial frontal and orbital gyri), the cingulate gyri and the insulae. Although we used exactly the same regions, our ROI mask differed in size with the ROI mask by Picó-Pérez et al. (2018). Our contact to the authors did not solve the issue.

Figure 1. A) Amygdala seed regions, blue = CMA, green = BLA; B) PFC ROI mask encompassing different regions of the frontal lobe, cingulate gyri, and insula (cf. Picó-Pérez et al., 2018).

2.6.1.2 Data preprocessing and analysis

Preprocessing and statistical analyses of resting state MRI data were carried out using the CONN toolbox (version 18b) pipeline (Whitfield-Gabrieli & Nieto-Castanon, 2012), SPM 12 (<https://www.fil.ion.ucl.ac.uk/spm/software/spm12/>) and Matlab 2019b (MathWorks, Natick, MA). Preprocessing of the functional scans included spatial realignment and unwarping, slice-time correction, and outlier detection (ART-based scrubbing). Next, DARTEL (Ashburner, 2007) was used to create a study-specific anatomical template. Subject specific normalization parameters were estimated for anatomical images. These parameters were then applied to the functional scans. Lastly, smoothing using an 8 mm Gaussian kernel was done. Prior to first-level analyses, a denoising procedure was applied to remove motion artifacts, physiological and other artifactual effects from the fMRI-signal. This procedure included the component-based correction method (Comp-Cor, Behzadi, Restom, Liau, & Liu, 2007) and temporal band-pass filtering of 0.008–0.09 Hz. To avoid potential ramping effects at the beginning of the session, CONN models the entire acquisition and includes an additional confounding variable as covariate in the denoising procedure. The six movement parameters and a matrix containing the ART-detected outliers were included as first-level nuisance covariates. Preprocessing of the structural scans included segmentation and normalization to the MNI reference brain.

For first level analysis, a general lineal model (GLM) was created which includes the four noise-corrected amygdala-seed time series as predictors. To check whole brain, basic rsFC of the four amygdala nuclei were computed both for whole sample as well as for the three experiments. All second-level analyses for hypotheses testing were restricted to the PFC mask. For second-level analysis of aim 1, separate multiple regression models were performed for each of the four amygdala seeds (left CMA, right CMA, left BLA, and right BLA). Dispositional reappraisal and suppression use served as predictors of interest to test for voxel-wise correlations between the seed-to-ROI connectivity values and ERQ subscales. For second-level analyses of aim 2, multiple regression models were performed for left and right amygdala seeds, respectively (each comprising the mean of both CMA and BLA nuclei) for hypotheses 2a) and 2b); and for each of the four amygdala seeds (*F*-Test for any effects among the four seeds) for hypotheses 2c) to 2e). Experiential reappraisal success (one predictor) served as predictor of interest. For

second-level analyses of aim 3, multiple regression models were performed for each of the four amygdala seeds (F -Test for any effects among the four seeds) for hypotheses 3a) to 3c). Neuronal reappraisal success (extracted mean activity from left BLA, right BLA, left CMA, right CMA during Negative Permit > Negative Detach, see 2.6.2) served as predictors of interest, and the mean of all four predictors was computed during second-level contrast analysis. For all analyses, number of experiment (1, 2, 3) served as covariate. The significance threshold was set to $p < .05$, family-wise error corrected (FWE) for multiple comparisons. For exploratory analyses, we lowered the threshold to $p < .001$ (uncorrected) and report respective results in the Supplementary Material.

2.6.2 Task-related neuronal reappraisal success - Data preprocessing and statistical analysis

Preprocessing and statistical analyses of functional MRI data were carried out using SPM 8 (<https://www.fil.ion.ucl.ac.uk/spm/software/spm8/>), SPM 12 (<https://www.fil.ion.ucl.ac.uk/spm/software/spm12/>), and Matlab 2019b (MathWorks, Natick, MA). The first four volumes of each run were discarded. Preprocessing included motion correction, coregistration of individual functional and anatomical images, spatial normalization (deviating from the preregistration) of the anatomical data to the MNI template, application of the estimated transformation parameters to the coregistered functional images using a resampling resolution of $2 \times 2 \times 2 \text{ mm}^3$, and spatial smoothing of the functional images (FWHM 8 mm). For first level analysis, a general linear model (GLM) was created with regressors based on experimental conditions (experiment 1: View Neutral, View Negative, Permit Negative, Detach Negative; experiment 2: Permit Neutral, Permit Negative, Detach Neutral, Detach Negative; experiment 3: Permit Neutral, Permit Negative, Detach Neutral, Detach Negative, Intensify Neutral, Intensify Negative), as well as six additional motion regressors of no interest. Instructions and picture were set together as one event. Temporal patterns were modeled as boxcar function (8 s duration (experiment 1 and 3) and 10 s duration (experiment two), respectively) to cover sustained responses. All regressors were convolved with the canonical hemodynamic response function (HRF). All runs of the imaging experiments were combined within one fixed-effects model.

To obtain scores for *neuronal reappraisal success*, mean activity of the amygdala for the contrast Negative Permit > Negative Detach was extracted for each participant using MarsBaR (<http://marsbar.sourceforge.net/>). Therefore, maximum probability maps of the left BLA, right BLA, left CMA, and right CMA were created using the SPM Anatomy toolbox v.2.2c (Eickhoff et al., 2005). The probability threshold was set to 40% for each voxel to provide a sufficient areal coverage of the anatomical structure (Baur et al., 2013; Eickhoff et al., 2006).

2.6.3 Dispositional ER and task-related experiential responses (self-report) - Statistical analysis

Analyses on task-related experiential responses (arousal ratings) and trait measures were conducted using R (<https://www.r-project.org/>). A Shapiro-Wilk test was performed to test variables for normal distribution. ERQ subscales (dispositional reappraisal and suppression use) were normally distributed ($p > .05$, see Supplementary Table S1). A paired t -test was conducted to check whether participants reported to use reappraisal strategies to an equal extent than suppression strategies. The PANAS subscale positive affect and task-related experiential responses were not normally distributed ($p < .05$, see Supplementary Table S1). Wilcoxon signed rank tests with continuity correction were conducted to check whether participants experienced positive and negative affect to an equal amount and to test whether task-related experiential

responses are significantly lower after using detachment, compared to permitting all upcoming emotions.

3 Results

3.1 Dispositional ER and task-related experiential responses (self-report)

The mean dispositional reappraisal and suppression scores (ERQ) are presented in Table 1 (for a comparison of all predictor variables across the three experiments see Supplementary Table S2). Participants reported using reappraisal ($M = 4.8$, $SD = 0.8$) to a significantly stronger extent than suppression ($M = 3.4$, $SD = 1.2$) ($t(100) = 9.1$, $p < .001$). Regarding positive and negative affect (PANAS), participants showed a significant higher experience of positive affect as compared to negative affect ($V = 5241$, $p < .001$). Correlation analyses showed a significant association between both PANAS subscales ($r = -.29$, $p = .003$), but none between ERQ and PANAS subscales ($p > .05$).

In the ER experiment, participants reported significantly lower task-related experiential responses after detachment from negative pictures, $M = -15.4$, $SD = 68.9$, compared to permitting emotions, $M = 13.6$, $SD = 59.8$, $V = 722.5$, $p < .001$. Therefore, the implementation of the instructed ER strategies in the experiment was successful (cf. Scheffel et al., 2019).

3.2 Resting-state functional connectivity results

3.2.1 Basic, whole brain functional resting-state connectivity (without PFC mask and covariate)

Functional connectivity patterns of basolateral (BLA) and centromedial (CMA) amygdala seeds and regions within whole brain for the whole sample without covariate are presented in Supplementary Figure S5. Overall, there were significant ($p > .05$ FWE-corrected) associations of left and right BLA and CMA nuclei with amygdala, nucleus caudate, precentral and postcentral gyrus, Rolandic operculum, middle cingulum, angular gyrus, middle temporal gyrus, middle occipital gyrus, hippocampus, superior temporal pole and inferior parietal gyrus (see Supplementary Tables S15 for a complete list of all associations).

Because of differences between experiments (see Supplementary Table S2), we repeated all analyses separately for each experiment. The results are reported in Supplementary Figures S2 (experiment 1), S3 (experiment 2), S4 (experiment 3), and Supplementary Tables S3 (experiment 1), S7 (experiment 2), S11 (experiment 3).

3.2.2 Aim 1: Replication dispositional emotion regulation and functional resting-state connectivity

Whole sample results (with PFC mask and covariate)

Functional connectivity patterns of left and right basolateral (BLA) and centromedial (CMA) amygdala seeds and regions within the PFC mask are presented in Supplementary Table S19. Overall, there were no significant associations of left and right BLA and CMA with any region within the PFC mask ($p > .05$ FWE-corrected). For explanatory purposes, we lowered the threshold to $p < .001$ uncorrected. We found meaningful associations (clusters $k \geq 10$ voxels) with superior orbitofrontal gyrus, supplementary motor area, inferior orbitofrontal gyrus, middle orbitofrontal gyrus, inferior frontal gyrus triangularis, superior frontal gyrus, insula, and Rolandic operculum.

Regarding dispositional emotion regulation, there were no significant correlations with rsFC of any of the four amygdala seeds, that is, neither dispositional reappraisal nor suppression use was positively or negatively correlated with rsFC between left and right BLA and CMA to any region within the PFC mask ($p > .05$ FWE-corrected). For explanatory purposes, we lowered the threshold to $p < .001$ uncorrected and found meaningful associations of dispositional emotion regulation (clusters $k \geq 10$ voxels) with rsFC between brain regions: Reappraisal use was positively correlated with rsFC between right CMA and left insula, right BLA and right middle cingulum as well as left inferior frontal gyrus triangularis. Suppression use was positively correlated with rsFC between left CMA and right superior medial frontal gyrus, right inferior frontal gyrus opercularis, and left middle cingulum; and between right CMA and left middle frontal gyrus as well as right superior frontal gyrus. Furthermore, suppression scores were positively correlated with rsFC between left BLA and left superior temporal gyrus and right inferior frontal gyrus; and right BLA and right superior frontal gyrus. The results are presented in Table 2 and Supplementary Table S20.

Table 2. Significant clusters associated with the four amygdala nuclei as seeds, restricted to PFC mask for reappraisal and suppression (aim 1)

Region	H	x	y	z	k	T	p-uncorr	p-FWE
<i>Reappraisal</i>								
<i>Left centromedial amygdala</i>								
No suprathreshold clusters								
<i>Right centromedial amygdala</i>								
Insula	L	-34	12	-14	49	4.16	<.001	.264
<i>Left basolateral amygdala</i>								
No suprathreshold clusters								
<i>Right basolateral amygdala</i>								
Middle Cingulum	R	4	-38	44	41	3.79	<.001	.602
Inferior Frontal Gyrus Triangularis	L	-54	38	20	10	3.64	<.001	.758
<i>Suppression</i>								
<i>Left centromedial amygdala</i>								
Superior Medial Frontal Gyrus	R	14	58	30	17	3.76	<.001	.645
Inferior Frontal Gyrus Opercularis	R	60	16	38	10	3.66	<.001	.744
Middle Cingulum	L	-8	-44	32	29	3.50	<.001	.882
<i>Right centromedial amygdala</i>								
Middle Frontal Gyrus	L	-30	20	44	34	4.30	<.001	.176

<i>Left basolateral amygdala</i>								
Superior Temporal Gyrus	L	-40	20	-16	11	3.67	<.001	.752
Inferior Frontal Gyrus Opercularis	R	56	16	36	15	3.50	<.001	.893
<i>Right basolateral amygdala</i>								
Superior Frontal Gyrus	R	18	24	40	23	4.29	<.001	.187

Note. Significance threshold for seed-to-voxel analyses set at $p < .001$ uncorrected. Only clusters with $k \geq 10$ are reported. Coordinates are given in MNI space. Amy, amygdala; R, right; L, left; H, Hemisphere.

Because of differences between experiments (see Supplementary Table S2) we repeated all analyses separately for each experiment. The results are reported in the following.

Experiment 1

Regarding dispositional emotion regulation, there were no significant correlations with rsFC of any of the four amygdala seeds, that is, neither reappraisal nor suppression use was positively or negatively correlated with rsFC between left and right BLA and CMA to any region within the PFC mask ($p > .05$ FWE-corrected). For explanatory purposes, we lowered the threshold to $p < .001$ uncorrected. The results are reported in Supplementary Table S4.

Experiment 2

Regarding the dispositional emotion regulation, there were no significant correlations with rsFC of any of the four amygdala seeds, that is, neither reappraisal nor suppression use was positively or negatively correlated with rsFC between left and right BLA and CMA to any region within the PFC mask ($p > .05$ FWE-corrected). For explanatory purposes, we lowered the threshold to $p < .001$ uncorrected. The results are reported in Supplementary Table S8.

Experiment 3

Regarding the dispositional emotion regulation, there were no significant correlations with rsFC of any of the four amygdala seeds, that is, neither reappraisal nor suppression use was positively or negatively correlated with rsFC between left and right BLA and CMA to any region within the PFC mask ($p > .05$ FWE-corrected). For explanatory purposes, we lowered the threshold to $p < .001$ uncorrected. The results are reported in Supplementary Table S12.

3.2.3 Aim 2 and aim 3: Extension to experiential and neuronal reappraisal success

The analyses were repeated with *experiential and neuronal reappraisal success*, respectively, as predictors of interest. Regarding experiential reappraisal success, there were no significant correlations with rsFC of left and right amygdala to any region within the PFC mask ($p > .05$ FWE-corrected). For exploratory purposes, we lowered the threshold to $p < .001$ uncorrected and found meaningful associations (clusters $k \geq 10$ voxels). Experiential reappraisal success was positively correlated with rsFC between left amygdala and left middle cingulum and left inferior frontal gyrus opercularis; and positively associated with rsFC between right amygdala and left middle cingulum (see Table 3 and Supplementary Table S21).

Table 3. Significant clusters associated with experiential reappraisal success with respective amygdala seeds, restricted to PFC mask (aim 2)

Region	H	x	y	z	k	T/F	p-uncorr	p-FWE
<i>Left amygdala (BLA + CMA)</i>								
Middle Cingulum	L	-14	8	32	17	3.76	<.001	.663
Inferior Frontal Gyrus Opercularis	L	-38	10	12	19	3.67	<.001	.756
<i>Right amygdala (BLA + CMA)</i>								
Middle Cingulum	L	-12	14	32	21	3.88	<.001	.510
Precentral Gyrus	R	46	6	28	39	3.63	<.001	.765
<i>Amygdala (Any nucleus)</i>								
No suprathreshold clusters								

Note. Significance threshold for seed-to-voxel analyses set at $p < .001$ uncorrected. Coordinates are given in MNI space. Amy, amygdala; R, right; L, left; H, Hemisphere; Only clusters with $k \geq 10$ are reported.

Regarding *neuronal reappraisal success*, there were no significant correlations with rsFC of left and right amygdala to any region within the PFC mask ($p > .05$ FWE-corrected). For exploratory purposes, we lowered the threshold to $p < .001$ uncorrected. However, we found no meaningful associations (all clusters $k < 10$ voxels, except one association with superior frontal gyrus; see Table 4 and Supplementary Table S22).

Table 4. Significant clusters associated with neuronal reappraisal success for amygdala nuclei as seeds, restricted to PFC mask (aim 3)

Region	H	x	y	z	k	F	p-uncorr	p-FWE
<i>Amygdala (Any nucleus)</i>								
Superior Frontal Gyrus	R	16	48	48	12	5.52	<.001	.894

Note. Significance threshold for seed-to-voxel analyses set at $p < .001$ uncorrected. Coordinates are given in MNI space. Amy, amygdala; R, right; L, left; H, Hemisphere; Only clusters with $k \geq 10$ are reported. Because of differences between experiments (see Supplementary Table S2) we repeated all analyses separately for each experiment. The results are reported in the following.

Experiment 1

Regarding *experiential reappraisal success*, there were no significant correlations with rsFC of any of the four amygdala seeds, that is, changes in arousal ratings were not positively or negatively correlated with rsFC between left and right BLA and CMA to any region within the PFC mask ($p > .05$ FWE-corrected). For explanatory purposes, we lowered the threshold to $p < .001$ uncorrected. The results are reported in Supplementary Table S5.

Regarding *neuronal reappraisal success*, there were no significant correlations with rsFC of any of the four amygdala seeds, that is, mean activity of the amygdala for the contrast Negative Permit > Negative Detach was not positively or negatively correlated with rsFC between left and right BLA and CMA to any region within the PFC mask ($p > .05$ FWE-corrected). For explanatory purposes, we lowered the threshold to $p < .001$ uncorrected. The results are reported in Supplementary Table S6.

Experiment 2

Regarding *experiential reappraisal success*, there were no significant correlations with rsFC of any of the four amygdala seeds, that is, changes in arousal ratings were not positively or negatively correlated with rsFC between left and right BLA and CMA to any region within the PFC mask ($p > .05$ FWE-corrected). For explanatory purposes, we lowered the threshold to $p < .001$ uncorrected. The results are reported in Supplementary Table S9.

Regarding *neuronal reappraisal success*, there were no significant correlations with rsFC of any of the four amygdala seeds, that is, mean activity of the amygdala for the contrast Negative Permit > “Negative Detach was not positively or negatively correlated with rsFC between left and right BLA and CMA to any region within the PFC mask ($p > .05$ FWE-corrected). For explanatory purposes, we lowered the threshold to $p < .001$ uncorrected. The results are reported in Supplementary Table S10.

Experiment 3

Regarding *experiential reappraisal success*, there were no significant correlations with rsFC of any of the four amygdala seeds, that is, changes in arousal ratings were not positively or negatively correlated with rsFC between left and right BLA and CMA to any region within the PFC mask ($p > .05$ FWE-corrected). For explanatory purposes, we lowered the threshold to $p < .001$ uncorrected. The results are reported in Supplementary Table S13.

Regarding *neuronal reappraisal success*, there were no significant correlations with rsFC of any of the four amygdala seeds, that is, mean activity of the amygdala for the contrast Negative Permit > Negative Detach was not positively or negatively correlated with rsFC between left and right BLA and CMA to any region within the PFC mask ($p > .05$ FWE-corrected). For explanatory purposes, we lowered the threshold to $p < .001$ uncorrected. The results are reported in Supplementary Table S14.

4 Discussion

The first aim of this investigation was to directly replicate the study by Picó-Pérez et al. (2018). We analyzed associations of *dispositional emotion regulation* (ER), that is the habitual use of reappraisal and suppression measured via self-report (Abler & Kessler, 2009), with functional resting-state connectivity (rsFC) between the amygdalae and PFC by reanalyzing data from 107 participants of an ER study. None of the hypotheses could be confirmed, that is, we could not statistically confirm associations of dispositional reappraisal and suppression use with rsFC between left and right basolateral and centromedial amygdala, respectively, and regions in the PFC (ACC and SMA) and the insula. Thus, we failed to replicate the results of Picó-Pérez et al. (2018).

Second, we extended the investigation of resting-state functional networks and ER to associations with *experiential reappraisal success*. This investigation was based on findings by Uchida et al. (2015). Following the recommendations of Zwaan et al. (2018) we aimed at a conceptual replication and hypothesized that experiential reappraisal success (measured via arousal ratings) is associated with rsFC between left and right amygdala and left insula, with rsFC between left and right amygdala and dmPFC, with rsFC between the amygdalae and vmPFC, as well as with rsFC between the amygdala and dlPFC. Again, none of our hypotheses could be confirmed.

Lastly and in order to extend the research question to *neuronal reappraisal success*, we added a third analysis. Data of the same sample was analyzed to examine the hypotheses of associations between neuronal reappraisal success (defined by amygdala downregulation during reappraisal in an ER task) with rsFC between the amygdalae and insula, rsFC between the amygdalae and dmPFC, and rsFC between the amygdalae and dlPFC. We were not able to find any significant correlations here either.

To clarify whether there were any basic problems in detecting resting state networks in our sample, we conducted a whole brain functional connectivity analysis without any additional predictors and without the covariate. This revealed that left and right basolateral and centromedial amygdala were negatively coupled with dlPFC, vlPFC, dmPFC, and dorsal ACC regions, and positively coupled with vmPFC, SMA, subgenual ACC as well as posterior cingulate gyrus and insula/vlPFC (see Supplementary Figure S5 and Supplementary Table S15). Overall, there is an overlap of these regions with the regions reported by Picó-Pérez et al. (2018), albeit not in the same direction. Similar connectivity maps have been reported by others Roy et al. (2009); (Tetereva et al., 2020; Weis, Huggins, Bennett, Parisi, & Larson, 2019). We

therefore assume that our resting state measurement has been successful in principle. However, when we included number of experiment as covariate in this basic functional connectivity analysis, none of the clusters showed significant coupling with amygdala anymore. Separate analyses of basic, whole brain rsFC of the amygdalae revealed variability between the three different sub-samples of our study (see Supplementary Figures S2, S3, and S4). However, this variability points to differences in strength rather than in the composition of the network.

There are several differences in methodology between the study of Picó-Pérez et al. (2018) and our study. Mainly, the differences refer to acquisition parameters of the functional MR images resulting, for instance, in a much lower spatial while slightly higher temporal resolution in Picó-Pérez et al. (2018). There were also differences in preprocessing of fMRI data and the statistical procedures (see Supplementary Table S23). Most importantly, we were not able to directly replicate the size of the PFC ROI for small volume correction. Although we followed the procedure laid out in the original study by Picó-Pérez et al. (2018), which resulted in a ROI of 17,391 voxels ($2 \times 2 \times 2 \text{ mm}^3$) in the original study, our mask contained 56,833 voxels ($2 \times 2 \times 2 \text{ mm}^3$). A visual comparison further points to some differences in coverage of the PFC, although the regions targeted by our hypotheses were included. Nevertheless, corrections for multiple comparisons had to be performed for a much smaller ROI in the Picó-Pérez study, which might have led to a higher possibility for smaller effects to reach statistical significance (see Figure 1). Moreover, differences are obvious regarding sample size and composition. The original study sample comprised 48 participants with a mean age of 39.6 years, while the participants in our study ($N = 107$) were much younger with a mean age of 24.4 years. Since emotion control, motives as well as choice of strategies change with age (e.g. Scheibe & Carstensen, 2010), this difference in mean age between the samples certainly plays a role. Because of the larger sample size, our study offers greater statistical power, which could have led to a reduced likelihood of false positive findings.

Nevertheless, with respect to aim 1, we did not achieve an exact but direct replication following Zwaan et al. (2018). A different definition of replications offer Brandt et al. (2014). They define close replications as studies that “aim to recreate a study as closely as possible, so that ideally the only differences between the two are the inevitable ones” (p. 218). With regard to this strict definition, we did not achieve a close replication of the Picó-Pérez study. However, we do not consider the differences in data acquisition and preprocessing to produce the failed replication, but the differences between the samples might at least partly explain the divergent results. However, we are of the opinion that a replication of the same results should be rather independent of the detailed methodology.

With respect to aim 2, the methodological differences between our study and Uchida et al. (2015) are more pronounced. While the samples’ mean age is very similar (see Supplementary Table S24), the sample size is larger in our study. Additionally, Uchida et al. selected their participants according to their ER abilities in order to achieve an equal distribution of their abilities. This was not the case in our study. Thus, the original study ensured a higher variability of their main construct, which might have increased the possibility of finding an effect. With respect to the operationalization of experiential reappraisal success, the original study instructed reinterpretation as ER strategy and measured trial-by-trial affect ratings (Uchida et al., 2015), whereas in our replication attempt distancing was used as ER strategy and trial-by-trial ratings were only implemented in one of our data sets. Additionally, all our experiments used arousal ratings. With this different operationalizations of a central construct, our replication attempt could be considered as conceptual (Zwaan et al., 2018) at best. In other words, “on a continuum from ‘close’ to ‘conceptual’” (Brandt et al., 2014) our replication attempt might be placed at the very end of the continuum. Thus, we can only conclude that the findings of the original study could not conceptually be replicated, the results do not extend to a different reappraisal

strategy nor to arousal instead of affect outcomes. Minor differences between the original and the replication can be found in data acquisition and processing, however, we consider these negligible (see Supplementary Tables S23 and S24 for a detailed comparison).

Our findings not only contrast with the two studies on which we based our *a priori* hypotheses (Picó-Pérez et al., 2018; Uchida et al., 2015), they also contradict a number of other studies that have identified patterns of intrinsic functional connectivity that differ between the dispositional use of ER strategies, or are associated with experiential and neuronal reappraisal success (Burr et al., 2020; Morawetz et al., 2016; Pan et al., 2018). Common to these studies is that regions in the default mode network have been identified. Particularly, the latest study by Burr et al. (2020) used the largest sample up to date ($N = 1316$) in a data-driven, theory-free approach and found that intrinsic connectivity of the default mode network was associated with dispositional use of suppression (but not reappraisal). Critically, the authors used general functional connectivity (GFC, Elliott et al., 2019) to leverage shared features of task and resting-state fMRI and circumvent reported reliability issues of resting state measures (e.g., Noble, Scheinost, & Constable, 2019). Thus, instead of focusing on connectivity in *a priori* regions of interest between cortical and subcortical areas, distributed networks of brain regions might be a more promising target in future studies as they take into account the complexity of the underlying neuronal processes.

4.1 Limitations

Several limitations have to be noted. First, to achieve a larger sample size and power, we combined three samples from three slightly different ER experiments. Although all experiments included the conditions and instructions relevant for the present study, subtle effects of experimental variation cannot be ruled out (e.g., experiment 3 included an intensify instruction that was not present in experiment 1 and 2). Therefore, we included experiment as covariate in all our analyses (see also Supplementary Table S2 for a comparison of all predictor variables across experiments). Related to the study design, the resting state measurement took place in a separate session approximately one week after the ER task. Although the investigated effects are supposed to be independent from each other (resting state vs. task related), unknown effects of time cannot be excluded since the experimental protocol was not randomized.

Second, the results regarding experiential reappraisal success are limited, because in experiment 2 and 3 arousal ratings were recorded retrospectively after each block. In the overall research question of the larger study we were interested in aftereffects of ER (see for instance Walter et al., 2009). However, an arousal rating after picture offset in the relaxation period would alter time courses of the HRF (Burklund, Creswell, Irwin, & Lieberman, 2014), thus, no trial-by-trial arousal rating was used while accepting the disadvantages of a retrospective arousal rating. Supplementary Table S2 presents the arousal ratings separately for each experiment. Indeed, the arousal ratings were higher for the trial-by-trial rating in experiment 1 compared to the retrospective ratings in experiment 2 and 3.

Third, the fixation of presented pictures was not controlled for via eye tracking. Therefore, we do not have an objective measure to assess whether participants fixated negative images as instructed. This could have led to a failed activation of brain regions related to emotional processing during the negative stimulation period and, subsequently, to difficulties in detecting a reappraisal success. However, analyses of brain activation during reappraisal of negative pictures as compared to viewing negative pictures revealed downregulation of amygdala activation as well as activation in prefrontal regions in a previous analysis of the same data (Scheffel et al., 2019) replicating earlier findings (Buhle et al., 2014; Dörfel et al., 2014; Paschke et al., 2016; Walter et al., 2009).

Finally, we have no information on whether detachment is the participants' preferred ER (reappraisal) strategy. It is possible that some participants use other forms of reappraisal in their everyday life, for example, reinterpretation. While performing the task, they might be more successful with their preferred instead of the instructed strategy. However, we tried to address this by a training session on the implementation of detachment before the scanner session.

4.2 Conclusion

In conclusion, the present preregistered replication study at least calls into question the reported findings on individual differences in resting state cortico-limbic functional connectivity related to dispositional use of ER strategies and even task-related, experiential and neuronal reappraisal success. The most parsimonious explanation for the lack of replication might be that these differences are either small or non-existent, and/or swamped by sample effects and methodological differences. As we are not able to finally answer this question, more replication studies are needed to enhance our understanding why and when a finding is generalizable or not. Furthermore, we remain optimistic that continued developments towards improving methodology in resting state measurement (enhancing reliability) and distributed network approaches will help to eventually reveal reliable patterns of functional connectivity underlying successful emotion regulation.

5 Conflict of Interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

6 Author Contributions

AG and DD contributed to the design of the study; AG and CS organized the database and performed the statistical analysis; DD, CS and AG wrote the first draft of the manuscript. All authors contributed to manuscript revision, read and approved the submitted version.

7 Funding

Data collection was funded by a CRC of the Deutsche Forschungsgemeinschaft (SFB 940, project A5).

8 Acknowledgments

We thank Kersten Diers and Alexander Strobel for their intensive work in conception and design of the overall study and Kersten Diers for data collection and providing the final data samples. We also thank Christin Haucke for her help with the statistical data analysis.

9 Data Availability Statement

The datasets generated and analyzed during this study can be found at the Open Science Framework [<https://osf.io/p7hb5/>].
