Running Head: SOCIAL COGNITION AND SOCIODEMOGRAPHIC CHARACTERISTICS

Social cognition or social class and culture? On the interpretation of differences in social
cognitive performance

Abstract

The ability to understand others' mental states carries profound consequences for our mental and physical health. Difficulty with mental state understanding (MSU) may predispose individuals towards social isolation, loneliness, and psychiatric illness, making efforts at validly and reliably assessing MSU of utmost importance. However, inspection of some of the more widely used tasks to assess MSU (e.g., the Reading the Mind in the Eyes Task) reveals potential assessment issues, namely, an ostensible reliance upon a participant's vocabulary/intelligence and the use of culturally-biased stimuli, among other issues. Here, using data from a sample of over 40,000 international, English-speaking participants, we evaluate the impact of demographic and sociocultural factors on several social cognitive tasks and one non-social cognitive task in order to assess whether the effect of participant characteristics is robust and reliable across social cognitive abilities or a function of task-specific characteristics, such as the use of uncommon vocabulary and/or ethnically homogenous stimuli. We find a pattern of results suggesting that social cognitive tasks may be biased against the less educated and those participants whose race/ethnicity differs from the task's stimuli; an effect potentiated in one of the more popular MSU tasks. Together, these data suggest that certain MSU tasks may be tapping social class and culture as much as it is social cognition.

Social cognition or social class and culture? On the interpretation of differences in social cognitive performance

Success in the social world hinges upon our ability to decipher and infer the hidden beliefs, emotions, and intentions of others. Indeed, a large body of research has demonstrated that our ability to understand others' mental states is associated with a variety of positive social outcomes including increased popularity (Slaughter, Imuta, Peterson, & Henry, 2015), improved interpersonal rapport (Blatt, LeLacheur, Galinsky, Simmens, & Greenberg, 2010; Todd, Bodenhausen, Richeson, & Galinsky, 2011), prosocial behavior (Imuta, Henry, Slaughter, Selcuk, & Ruffman, 2016), positive evaluations of the perspective-taker (Goldstein, Vezich, & Shapiro, 2014), and the well-being of perspective-taking recipients (Dodell-Feder, Felix, Yung, & Hooker, 2016), among many other outcomes (Todd & Galinsky, 2014). In contrast, difficulty with mental state understanding and disruption to its neural bases is associated with a variety of negative outcomes, including friendlessness (Fink, Begeer, Peterson, Slaughter, & de Rosnay, 2015), social amotivation and isolation (Dodell-Feder, DeLisi, & Hooker, 2014; Dodell-Feder, Tully, Lincoln, & Hooker, 2014), and risk for severe psychiatric illness, such as schizophrenia-spectrum disorders (Kim et al., 2011). These findings are even more sobering when considering the robust relationships among social isolation, psychiatric illness, and mortality (Holt-Lunstad, Smith, Baker, Harris, & Stephenson, 2015; Walker, McGee, & Druss, 2015). Taken together, at worst, poor MSU may be associated with decreased longevity; at best, poor MSU may be associated with a decline in mental and physical well-being. Either way, the health consequences of MSU are not to be ignored.

For these reasons, the importance of valid and reliable assessments of MSU could not be overstated. Failure to detect MSU impairments could lead researchers and clinicians to overlook

etiological factors, fail to identify someone at risk leading them on a path towards mental and physical health decline, or incorrectly conclude that a treatment is efficacious when it is not. On the other hand, detecting impairments when they do not exist could lead researchers and clinicians on a wayward path of research to elucidate a specious causal pathway, misidentify someone as being at-risk for psychopathology leading to stigma and unnecessary and costly interventions, or incorrectly conclude that a treatment is not efficacious when it is. Said simply, inaccurate MSU assessment may carry deleterious consequences for every area of clinical research, from the study of etiology, risk, and treatment.

Do we have valid and reliable assessments of MSU? In light of the assessment issues highlighted above and their potential consequences, this question has appropriately been taken up by several initiatives at the National Institute of Mental Health (NIMH; National Advisory Mental Health Council Workgroup on Tasks and Measures for RDoC, 2016; Pinkham, Harvey, & Penn, 2017). The answer to this question, as per the NIMH (National Advisory Mental Health Council Workgroup on Tasks and Measures for RDoC, 2016), is unclear. What is clear is that there are favorite measures among researchers assessing MSU. Likely the most widely-used task to assess MSU is the Reading the Mind in the Eyes Task (RMET; Baron-Cohen, Wheelwright, Hill, Raste, & Plumb, 2001), which is also the current NIMH recommended task for assessing mental and emotional perspective-taking^a MSU as detailed in a 2016 report by the National Advisory Mental Health Council Workgroup on Tasks and Measures for Research Domain Criteria (RDoC; National Institute of Mental Health, 2016). In the RMET, participants view 36 black-and-white photographs, originally selected from magazine articles, of solely the eyes of

^a The *Systems for Social Processes* subgroup also recommended the Hinting Task as the best option for logical/physical perspective taking.

Caucasian female and male actresses/actors. Participants decide which of four adjectives (e.g., *panicked, incredulous, despondent, interested*) best describes the mental state being expressed in the eyes with the correct answer having been generated through consensus ratings. As of early 2018, the paper detailing the revised version of the test (Baron-Cohen, Wheelwright, Hill, et al., 2001) has been cited close to 1,900 times (Web of Science); the RMET has been translated into at least 24 different languages (https://www.autismresearchcentre.com/arc_tests) reflecting its widespread, international use; the RMET is used more than any other measure of MSU in the psychopathology literature (see the following meta-analyses on schizophrenia, Bora & Pantelis, 2013 and Bora, Yucel, & Pantelis, 2009; bipolar disorder, Bora, Bartholomeusz, & Pantelis, 2016); and autism, Chung, Barch, & Strube, 2014) as well as other fields of study (Dodell-Feder & Tamir, 2017); the RMET is often used in neuroimaging studies of MSU (Molenberghs, Johnson, Henry, & Mattingley, 2016); and the RMET has been used in clinical trials (Anagnostou et al., 2012). Taken together, well over a decade of research on MSU has largely been based on findings from this task.

What explains the popularity of the RMET? In addition to being quick to administer and highly tolerable by participants (Pinkham, Harvey, et al., 2017), exhibiting sensitivity to clinical impairment, and having its neural bases well-studied, it is often considered to represent an “advanced test” (Baron-Cohen, Wheelwright, Spong, Scahill, & Lawson, 2001, p. 241) of MSU as it requires participants to decode nuanced facial expressions and match them to a lexicon of nuanced intrapersonal states. As an ostensible consequence of the task’s complexity, it has minimal ceiling effects (Olderbak et al., 2015; although see Black, in press), which often plagues other MSU tasks (see Dodell-Feder, Lincoln, Coulson, & Hooker, 2013 for a brief discussion). That said, inspection of the task reveals some potential issues. For example, task performance is

moderately-to-strongly associated with vocabulary (Olderbak et al., 2015), IQ (Baker, Peterson, Pulos, & Kirkland, 2014), and educational attainment (Warrier et al., 2018); perhaps unsurprising given the complex and uncommon vocabulary used as response options (e.g., *aghast*, *tentative*). Additionally, the mental states of the target are actually unknown and consensus scoring leaves open the possibility that accuracy depends on sharing social norms and beliefs regarding how mental states may be expressed in eyes with the consensus raters (Johnston, Miles, & McKinlay, 2008). In a similar vein, most of the female stimuli depict young women who are wearing cosmetic products, and revealing a limited number of gender normative mental states^b, in a way that may be very different to how women are depicted in other cultures. These concerns are borne out in research revealing sociocultural differences in RMET performance (Adams et al., 2010; Prevost et al., 2014). Of course, the RMET is not unique in these respects. Other MSU tasks suffer from many of the same issues (Corcoran, Mercer, & Frith, 1995; Dodell-Feder et al., 2013; McDonald, Flanagan, Rollins, & Kinch, 2003) through reliance on verbal ability, the use of racially/ethnically homogenous stimuli, or the depiction of social scenarios in which participants may come to a very different understanding of the characters, not because of poor MSU ability, but because of cultural differences in how they understand the broader social context (although see Kohler et al., 2003 for an example in which the issue of stimulus race/ethnicity is appropriately dealt with; see Nisbett, 2004 for a general discussion of cultural differences in cognition). That said, all of these issues are present in the

^b For example, correct response options for female faces include words with sexual connotations such as *desire*, *flirtatious*, and *fantasizing*; correct response options for male faces include words with aggressive or power connotations such as *insisting*, *accusing*, *defiant*, *hostile*, and *serious*. Additionally, as determined with Linguistic Inquiry and Word Count (LIWC) software (Pennebaker, Boyd, Joran, & Blackburn, 2015), correct response options for female faces include more positive emotion words (41.8%) than for male faces (10.5%), and correct response options for male faces include more negative emotion words (36.8%) than for female faces (17.7%).

RMET, and the available evidence suggests that performance on this task may be particularly affected by factors that are associated with social class (i.e., education, IQ) and culture (i.e., race, ethnicity).

Here, leveraging four massive web-based datasets of the RMET and other social and non-social cognitive tasks, totaling over 40,000 international, native- or primarily-English speaking participants, we evaluate whether and to what extent performance on social cognitive tasks, and the RMET in particular, is influenced by demographic and sociocultural factors, including age, gender, education, race, and ethnicity. Said otherwise, we ask whether performance on these tasks is contaminated by sociodemographic factors associated with class and culture, among other factors. In doing so, we hope to inform efforts aimed at identifying, creating, and disseminating valid and reliable measures for the assessment of constructs that may be used in future diagnostic systems.

40,248 international, native- or primarily-English-speaking participants between the ages of 10 and 70, completed one of five measures: (1) the original RMET (RMET-36), (2) a shortened version of the RMET (RMET-16; described in the Methods), (3) a measure of emotion identification requiring participants to label the emotions of multiracial stimuli (henceforth, “multiracial emotion identification”), (4) a measure of emotion discrimination requiring participants to make *same/different* judgements regarding the emotions expressed in Caucasian faces, and (5) digit symbol matching, which is a non-social, non-verbal measure of processing speed tapping visual working memory and sensorimotor speed.

To understand how task characteristics might impact the relationship between sociocultural factors and MSU performance, we selected four tasks that differed in stimulus and task parameters, including racial diversity of faces and reliance on vocabulary. This allowed us

to test several possibilities regarding the influence of sociocultural factors on MSU performance (Table 1); that is, whether the relations between sociocultural factors and measure performance is the result of the measure being (a) social (RMET, multiracial emotion identification, emotion discrimination) versus non-social (digit symbol matching^c), (b) requiring emotion labelling (RMET, multiracial emotion identification) versus no emotion labelling (emotion discrimination, digit symbol matching), (c) using uncommon vocabulary (RMET) versus common vocabulary/no vocabulary (multiracial emotion identification, emotion discrimination, digit symbol matching)^d, and (d) using Caucasian-only (RMET, emotion discrimination) versus non-Caucasian-only or no face stimuli (multiracial emotion identification, digit symbol matching). To evaluate the aforementioned possibilities, we compared effect size relationships between task performance and different demographic and sociocultural characteristics across tasks, including race, ethnicity, education, gender, and age.

Methods

^c We chose digit symbol matching as the nonsocial task because of its non-specific sensitivity to a variety of demographic factors, for example, age (Hartshorne & Germine, 2015), intelligence and cognition (Salthouse, 1996), neurological health (Longstreth et al., 2005), mental health (Dickinson, Ramsey, & Gold, 2007), and mortality (Fried, 1998). Said otherwise, performance on this task appears to have widespread *robust* and *meaningful* correlates. Thus, associations between digit symbol matching performance and demographic factors may serve as an informal baseline for possible relations between performance on the other measures and demographic factors.

^d We used the Corpus of Contemporary American English (Davies, 2010) to calculate the word frequency of the response options for the RMET, the emotion identification measure (*happy, sad, angry, fearful*), and the emotion discrimination measure (*same, different*). The response options for RMET were massively less frequent compared to the response options for the emotion identification task, $d=2.1$, 95% CI [1.02, 3.13], common language effect size [CLES]=92.9% and emotion discrimination task, $d=22.3$, 95% CI [18.8, 25.8], CLES=100%. Said otherwise, there is a 93% chance that a randomly selected response option from the emotion identification task will be more frequent than a randomly selected word from the RMET; and, there is a 100% chance that a randomly selected response option from the emotion discrimination task will be more frequent than a randomly selected response option from the RMET.

Participants

Participants were an international sample of 40,248 native or primarily English-speaking internet-users between the ages of 10 and 70 ($M=29.5$, $SD=14.36$; 57.3% female) who visited the non-profit research initiative website TestMyBrain.org between 2010-2017 (Table 1). No explicit recruitment was performed. Instead, participants come to TestMyBrain.org through search engine results, social-networking websites, or by word of mouth. As such, the participants represent a non-random sample leaving open the possibility of self-selection effects. However, prior research using TestMyBrain.org has shown that the data are reliable and comparable in terms of quality to data collected in the lab (Germine et al., 2012), and mirror findings from nationally representative, population-based samples (Hartshorne & Germine, 2015), suggesting that the potential impact of self-selection effects is likely to be minor.

Most participants were from countries in which the majority of the population are English-speaking and White/European (i.e., USA, Canada, Great Britain, Ireland, Australia, New Zealand, $n=31,310$, 77.8%; $n=6,085$, 15.1% were from non-predominantly-White/English-speaking countries; no data were available for $n=2,853$, 7.1% of participants). Prior to completing one of the measures described below, participants provided informed consent by electronically signing a form in a manner approved by the Harvard University Committee on the Use of Human Subjects in Research. After completing one of the measures, participants voluntarily provided demographic and sociocultural information including age, gender, education, race, and ethnicity. No personal identifying information was collected in order to avoid social desirability responding. A subset of the participants included in the current study have been included in other published studies (Germine & Hooker, 2011; Hartshorne & Germine, 2015).

Measures

Reading the Mind in the Eyes Task. In the RMET (RMET-36), participants are presented with 36 pictures of solely the eye-region from white actors and actresses taken from magazine photographs. Participants are instructed to select which of four adjectives best describes what the person in the picture is thinking or feeling. Each item is scored as *correct* or *incorrect*; thus, scores can range from 0-36. The RMET's psychometric properties have been well-studied. On reliability, internal consistency is typically poor, although test-retest reliability estimates are generally acceptable (Olderbak et al., 2015). On validity, RMET scores tend to correlate with scores on other measures of social cognition (Olderbak et al., 2015), differentiates clinical groups with well-documented social cognitive impairments (e.g., schizophrenia, autism) from healthy participants (Chung et al., 2014), and is predictive of functioning in clinical samples (Pinkham, Harvey, et al., 2017).

One possibility is that prior findings relating RMET performance to sociocultural factors is the result of task heterogeneity; that is, while performance for most stimuli load onto a single MSU-related factor that is relatively unbiased, there may also exist low quality items that tap more into education and sociocultural biases (e.g., items with complicated vocabulary words), which might also account for the relatively low internal reliability of the task. Based on analyses by Olderbak and colleagues (Olderbak et al., 2015), we took a subset of 16 items from the RMET that load most strongly onto a single common factor which we might assume *a priori* indexes MSU performance, and had part of our sample complete this 16-item version of the RMET (RMET-16), which represents a more homogeneous stimulus set.

Multiracial Emotion Identification Task. The multiracial emotion matching task is an emotion identification task where the participant has to indicate whether each of a set of 48 faces

is happy, sad, angry, or fearful. Faces represent a broad range of adult ages and race/ethnicities, with approximately equal proportions of men and women.

All tasks have been used in other studies and are described elsewhere, except for the Multiracial Emotion Identification Task. To develop this task, we recruited actors from across a range of ages and race/ethnicities, from the Boston Company One theater, as part of the Act Out for Brain Health project. Boston Company One theater has a mission of engaging the city's diverse communities, with an emphasis on diverse actors. Images were taken from video clips of actors portraying different emotions. An initial set of 146 images were selected portraying anger, fear, happiness, sadness, and neutral facial expressions to create an item bank. Images were drawn from this item bank and data was collected from a development sample of $N=8,309$ participants who each saw a subset of 37-53 images. Ultimately, the neutral condition was dropped as these faces were judged with significantly ($ps<0.01$) poorer reliability than anger, fear, sadness, and happiness (average correlation with rest of items for each emotion category: anger: $r=0.3$; fear: $r=0.26$; sadness: $r=0.2$; happiness: $r=0.25$; neutral: $r=0.06$). The reliability of judgements of other emotions did not significantly differ from each other ($ps>0.1$). The final test includes 48 images that were selected to capture (1) images with consistent judgments of a single emotion, (2) varying levels of difficulty for each emotion, and (3) items with high correlations with overall emotion recognition accuracy to maximize reliability, while preserving the diversity of actors and faces.

Emotion Discrimination Task. We assessed emotion discrimination with using the same stimuli and procedure as in prior studies of emotion discrimination (Garrido et al., 2009; L. Germine & Hooker, 2011; L. T. Germine, Garrido, Bruce, & Hooker, 2011; Pitcher, Garrido, Walsh, & Duchaine, 2008). Briefly, stimuli consisted of grayscale and cropped pictures of six

white female Ekman faces expressing either happiness, sadness, surprise, fear, anger or disgust. Pairs of faces were presented sequentially for 500 ms per face with a 500 ms inter-stimulus-interval. Participants were given up to 7 s to indicate whether the faces were expressing the same or a different emotion. There were an equal amount of face pairs depicting the same and different emotions. Prior work using variants of this task has demonstrated that performance on this task selectively taps emotion discrimination per se, and not more general aspects of face processing, such as identity discrimination (Pitcher et al., 2008). Furthermore, behavioral and neural response to this task has been shown to track with psychosis vulnerability (Germine & Hooker, 2011; Germine et al., 2011).

Digit Symbol Matching. The digit symbol matching task is modeled on the Digit Symbol Coding/Substitution tests from the Wechsler Adult Intelligence Scales. In this task, participants are presented with a key where numbers are paired with symbols. The participant is then shown a single symbol and has to indicate which number goes with that symbol. Scores are how many symbols a participant correctly matches in 90 seconds. This is a measure of processing speed that taps visual working memory and sensorimotor speed.

Data Analysis

Data were analyzed in R (R Core Team, 2017). Participants who did not report relevant demographic/sociocultural information were excluded on an analysis-by-analysis basis. Extreme values were transformed using a 95% Winsorization and z -scored to facilitate cross-task comparisons. Findings were considered statistically significant at $p < .05$ (two-sided) with correction for multiple comparisons (i.e., post-hoc Tukey HSD for simple effects and Bonferroni-adjusted p values for omnibus ANOVAs and t -tests). All analyses are accompanied by relevant effect sizes for group differences (Cohen's d and the Common Language Effect Size

[CLES] which denotes the probability that a randomly selected score from one group will be larger than a randomly selected score for another group) and variance accounted for (adjusted R^2 , η^2).

The relation between age and task performance was analyzed using segmented regression (Muggeo, 2003, 2008). In segmented regression, multiple linear segments are used to model non-linear changes between two variables. This analysis allows for an estimation of *breakpoints* (i.e., ages in which the relation between age and performance changes), and rates of change (i.e., the slope of the linear segments) before and after the breakpoint. Using AIC and BIC values to evaluate model fit, first, we confirmed that the relation between age and performance was non-linear (which was true for all measures) by comparing linear models to two segment models, and then iteratively tested models with an additional segment until model fit did not improve (i.e., AIC/BIC values did not decrease). In cases where the differences in AIC and BIC values between models were discrepant, we report the more conservative, parsimonious model with fewer segments. All other variables were categorical and group differences were assessed with Welch's t -tests or ANOVAs and post-hoc Tukey HSD tests. Since we find that for some measures, the effect of gender and age were moderate-to-large, and education, race, and ethnicity in our dataset were non-independent, we conducted an additional set of analyses for each factor controlling for all other factors (including the non-linear effect of age). To simplify these simultaneous regression models, we dichotomized education into high (grad, college, some college) and low (high, middle) categories and race into European/White and non-European/non-White categories. To evaluate cross-task differences among the levels of each factor, we examine and report effect sizes and their 95% CIs.

Data Availability

The data analyzed during the current study are available in the Open Science Framework repository at https://osf.io/st9ek/?view_only=737a23e58ce748fa8803aebfa0b42d4b.

Results

Participant characteristics and descriptive statistics from each task are presented in Table 2. Statistics are reported in full in the Supplementary Materials.

Age

We used segmented regression to evaluate performance over the lifespan. This method allows for an estimation of breakpoints and their 95% CIs, which are ages at which the relation between age and performance changes. Lifespan changes in digit symbol matching were best fit by a three-segment model in which performance steeply rose, $b=.152$, 95% CI [.136, .168], until age 17.16 years, 95% CI [16.82, 17.51], when performance peaked over the lifespan. After this age, performance began decreasing, $b=-.015$, 95% CI [-.019, -.011], and at age 35.29 years, 95% CI [32.64, 37.94], began decreasing at a significantly greater rate, $b=-.040$, 95% CI [-.043, -.037]. These lifespan changes replicate prior reports of lifespan changes in cognition (Salthouse, 2004), confirming that our sampling approach captured individual differences in performance in a way that replicates traditional studies. On the social cognitive tasks, performance across the lifespan was distinct from digit symbol matching, but largely similar between the tasks with one potentially important difference. In all social tasks, performance rose steeply from pre-adolescence to early adulthood (Figure 1A) with the first breakpoint occurring for multiracial emotion identification at age 16.43, 95% CI [15.29, 17.57], and the last breakpoint occurring for emotion discrimination at age 21.85 (95% CI [20.31, 23.38], with a breakpoint for RMET occurring in between these ages. For multiracial emotion identification and emotion discrimination, the age of these breakpoints represents peak performance with performance

leveling off after these breakpoints, and exhibiting no significant change in either direction across the rest of the lifespan, multiracial emotion identification second slope, $b < .001$, 95% CI [- .002, .002], emotion discrimination second slope $b = -.002$, 95% CI [- .005, .001]. However, RMET performance continues to rise after its breakpoint, though at a slower rate than in adolescence, RMET-36 second slope $b = .006$, 95% CI [.005, .008], RMET-16 second slope $b = .005$, 95% CI [.002, .007]. Results were unchanged when controlling for gender.

To summarize, performance on all measures exhibits a steep rate of improvement through adolescence, reaching a relatively similar breakpoint in late adolescence/early adulthood, between the ages of approximately 16 and 22. For all measures except for RMET, this is where performance peaks, after which performance either significantly declines, as with digit symbol matching, or remains stable, as with multiracial emotion identification and emotion discrimination. In contrast, performance on RMET continues to increase with age; an effect only typically observed with crystallized cognitive abilities, such as vocabulary or knowledge, which increase over the lifespan (Hartshorne & Germine, 2015). This suggests that in contrast to other social cognitive skills, in which performance peaks in late adolescence/early adulthood, performance on RMET may reflect the contribution on vocabulary or some other variable important to complex MSU, which continues to increase over the lifespan.

Gender

Females outperformed males on all social tasks, $ts > 5.43$, $ps < .001$, with comparable, small, effect sizes ranging from $d = .16$, 95% CI [.10, .22], common language effect size (CLES) = 54.48% on multiracial emotion identification to $d = .26$, 95% CI [.21, .31], CLES = 57.36% on RMET-16 (Figure 1B). The similar direction and magnitude of these effects across social cognitive tasks suggests a robustness to the female advantage in social cognition.

However, female advantage was specific to social cognitive tasks. On digit symbol matching, males outperformed females, $t(15,540)=-7.08$, $p<.001$, with the difference being smaller in magnitude than the gender difference in social cognition, $d=-.11$, 95% CI $[-.14, -.08]$, CLES=46.81%.

Education

There was a clear education effect across all tasks, individual task ANOVA $F_s>8.97$, $p_s<.001$, such that participants with higher education generally outperformed those with less education, with the biggest differences occurring between those with the highest levels of education (graduate school, college) and lowest levels (middle school). That said, education effects varied substantially across tasks. Education explained 1.35 times more variance in RMET-36 performance, $\eta^2=.0597$, 95% CI $[.0501, .06914]$, than the other racially homogenous measure, emotion discrimination $\eta^2=.0441$, 95% CI $[.0311, .0571]$, 7.96 times more variance than the other measure which used multiracial stimuli, multiracial emotion identification $\eta^2=.0075$, 95% CI $[.0029, .0125]$, and 6.78 times more variance than the nonsocial measure, digit symbol coding $\eta^2=.0088$, 95% CI $[.0058, .0119]$ (Figure 2A). Moreover, group differences were more reliable and biggest in magnitude for both versions of the RMET (RMET-36 and RMET-16: all post-hoc differences were significantly except graduate vs college education), with effect sizes ranging from $d=.04$ - 1.05 , CLES=51.12-77.14% for RMET-36 and $d=-.01^e$ -.81, CLES=49.68-71.59% for RMET-16. In contrast, more highly educated participants less consistently outperformed less educated participants for emotion discrimination, multiracial emotion identification, and digit symbol matching, with effect sizes in the small-to-large range

^e Negative effect size indicates that a group with less education outperformed a group with greater education.

for emotion discrimination, range $d=.09-.72$, CLES=52.41-69.38%, and small-to-moderate range for multiracial emotion identification, range $d=-.05-.39$, CLES=48.56-60.80% and digit symbol matching, range $d=-.17-.39$, CLES=45.09-60.98%. Together, the pattern of results suggests that while better education is associated with better performance across cognitive and social cognitive measures, this effect is magnified with the RMET (i.e., the magnitude of education level differences on performance is generally larger with the RMET versus the other measures). Furthermore, we observed comparable education effects on digit symbol coding and emotion identification, the social cognitive task that uses multiracial/multiethnic stimuli. This suggests that the effect of education on social cognitive performance can be mitigated with culturally diverse stimuli and/or reduced vocabulary demands.

Ethnicity

NIH-defined ethnicity (i.e., Hispanic or Latino ancestry) explained 8.55-26.47 times more variance in the RMET than it did in the other tasks, and only impacted performance on RMET-36, $t(610)=6.80$, $p<.001$, which was replicated with the RMET-16, $t(492)=6.01$, $p<.001$, such that non-Hispanic participants outperformed Hispanic participants (Figure 2B). These differences were small-to-moderate in magnitude, RMET-36 $d=.33$, 95% CI [.25, .42], CLES=59.28%, RMET-16 $d=.31$, 95% CI [.22, .41], CLES=58.81%. In contrast, no difference was observed between non-Hispanic and Hispanic participants for any other task, $ts>.88$, $ps>.300$, range $d=-.06-.11$, CLES=48.22-52.98%. Since effects of ethnicity are not observed with the other tasks, it suggests that the race effect may be specific to RMET performance per se and not social or non-social cognition more broadly.

Race

We observed an effect of race on all tasks, $F_s > 13.70$, $p_s < .001$; however, race explained 2.31-9.89 times variance in RMET performance, RMET-36 $\eta^2 = .0476$, 95% CI [.0386, .0568], RMET-16 $\eta^2 = .0658$, 95% CI [.0530, .0787], as compared with other tasks, multiracial emotion identification $\eta^2 = .0207$, 95% CI [.0126, .0294], emotion discrimination $\eta^2 = .0130$, 95% CI [.0058, .0213], digit symbol matching $\eta^2 = .0067$, 95% CI [.0040, .0096] (Figure 2C). Further, the differences between European/White versus non-European/non-White backgrounds differed by task. Specifically, in the RMET-36, European/White participants outperformed all other groups, ($p_s < .001$); an effect replicated in the RMET-16 dataset ($p_s < .001$). These differences were moderate-to-large in size, RMET-36 range $d = .55-.75$, CLES=65.02-70.32%, RMET-16 range $d = .56-1.00$, CLES=65.34-76.09%, with largest differences between African/Black and European/White participants. In contrast, on other tasks, European/White participants less consistently outperformed non-European/non-White participants. For example, on multiracial emotion identification, European/White participants performed no differently than Black/African or Native American/Alaskan Native participants; on emotion discrimination, European/White participants performed no differently than Native American/Alaskan Native participants; on digit symbol matching, European/White participant performed no differently than Asian participants (all $p_s > .05$). Furthermore, the effect sizes for these differences were lower for all comparisons, multiracial emotion identification range $d = .16-.41$, CLES=56.46-61.30%, emotion discrimination range $d = .18-.40$, CLES=55.06-61.23%, digit symbol matching range $d = .01-.36$, CLES=50.53-63.00%. Thus, while European/White participants tended to non- non-European/non-White participants, this difference was only reliable and large in magnitude in the RMET compared to all other tasks.

Additional Analyses

We re-ran analyses evaluating the separate effect of education, ethnicity, and race on performance, controlling for all other factors, including gender and the non-linear effect of age. All findings were unchanged.

Discussion

Findings from the current study suggest that the RMET may be unduly sensitive to several sociocultural factors over and above other social and non-social cognitive tasks. Specifically, the RMET appears to be more sensitive to demographic and sociocultural factors such that older, more highly educated individuals of non-Hispanic and White/European backgrounds are likely to outperform their younger, less educated, Hispanic and non-White/non-European counterparts. For the other tasks, we found similar trends in that those more highly educated tended to outperform those less educated and that participants reporting European/White race tended to outperform participants reporting non-European/non-White race. This pattern of results whereby the influence of variables were similar in nature (although not necessarily magnitude) across tasks suggest that education, ethnicity, and race may in fact be associated with social cognitive ability in a reliable way; a finding that may be consistent with an increasing literature documenting the deleterious effects of socioeconomic disadvantage on the brain and cognition (Glymour & Manly, 2008; Hackman, Farah, & Meaney, 2010; Zsembik & Peek, 2001).

However, the effect of sociocultural variables on RMET performance are potentiated in a way that it in theory should not. Consider the finding that people with schizophrenia- or autism-spectrum disorders perform worse than healthy controls on the RMET with an effect size (Hedges' g) of .73 and .81, respectively (Chung et al., 2014). Is there *a priori* reason to believe that on the original RMET, performance differences should be *similar* or *greater in magnitude*

between participants reporting European/White versus African race ($d=.75$)? Or between participants with some college/college/graduate versus middle school education ($d=.84$, $d=1.05$, $d=1.03$, respectively)? Said otherwise, is it reasonable to expect these groups to perform as differently from other groups as clinical populations with marked social impairment?

In theory, some of the sociocultural-RMET performance relations could be explained in a way that has nothing to do with limitations of the task. For example, regarding the lifespan findings, one possibility is that with age comes more social experience and expertise that would contribute to continually improving performance on RMET over the lifespan. Something similar could be occurring with education in that more time spent in school with one's peers, navigating what might be complex social networks, may similarly positively impact social cognitive ability, explaining the large magnitude of effect that education has on RMET performance, which is consistent with other findings (Warrier et al., 2018). However, if that were the case, we would expect to see similar increases in performance across the lifespan in the other social tasks, and for education to have a similar magnitude of effect on the other social tasks, which we do not. The lifespan findings with the RMET also stand in contrast to other work demonstrating a decline in social cognitive ability over the lifespan using other MSU tasks (Klindt, Devaine, & Daunizeau, 2017; Moran, Jolly, & Mitchell, 2012; Joseph M. Moran, 2013). Our findings support the notion that something unique is contributing to RMET performance. It could be that age and education are serving as a proxy for verbal ability and IQ, which increases across the lifespan (Hartshorne & Germine, 2015) and has been shown to affect RMET performance (Baker et al., 2014; Olderbak et al., 2015). It is interesting though that performance on multiracial emotion identification, which is similar in structure (i.e., requiring emotion labelling) to the

RMET, did not increase across the lifespan, and was not as related to education. This further suggests that the RMET may be particularly associated with these variables.

Regarding ethnicity and race, the RMET was the only task affected by NIH-defined ethnicity, and though White/European participants tended to outperform non-White/non-European participants across measures, these differences were less robust, and not as strong as they were with the RMET. Again, the relation between race/ethnicity and RMET could also seemingly be explained by other factors. For example, other research has revealed cultural differences in aspects of mental state understanding that might affect how European/White versus non-European/non-White participants may approach the RMET (Adams et al., 2010; Mason & Morris, 2010; Masuda et al., 2008). However, if this were the case, again, we would expect to see similar performance differences among race/ethnic groups in all social tasks, which we do not. Ethnic differences were least robust for the only non-social cognitive task (digit symbol matching) and the only social cognitive task with multicultural/multiracial stimuli (multiracial emotion identification). Further, the robust racial and ethnic group differences observed on the RMET do not appear to be simply the use of non-multiracial/multiethnic stimuli: ethnic differences were also less reliable and robust for emotion discrimination, which similarly contained ethnically homogeneous (Caucasian) stimuli. The current findings, taken with other research documenting cultural differences in performance on the RMET (Prevost et al., 2014), but not other MSU tasks (Bradford et al., 2017), suggest particular cultural bias with the RMET.

The RMET does appear to pick up on at least one reliable and robust demographic influence, that being gender differences. Across all social tasks, females outperformed males, which was a small, but reliable effect. This finding is consistent with other research on the RMET (Baron-Cohen et al., 2015; Kirkland, Peterson, Baker, Miller, & Pulos, 2013; Warrier et

al., 2018) and other social cognitive tasks (Kret & De Gelder, 2012). This cannot be explained by general performance differences favoring females since males outperformed females on digit symbol matching.

The implications of these findings are somewhat troubling, particularly given the task's widespread use. Performance on the RMET seems to reflect aspects of social class and culture as much as it does social cognitive ability. With respect to clinical investigations, this confound can be particularly harmful. Given shared variance between social status and risk for psychiatric illness (Kendler, 1996; McLaughlin et al., 2011), using the RMET, it would be difficult to tell whether performance differences are the result of psychopathology versus factors that covary with psychopathology, namely, socioeconomic class and culture.

How then should the field proceed? We see several ways forward. First and foremost, researchers using the RMET or tasks with similar characteristics (i.e., high reliance on vocabulary; racial and ethnic stimuli homogeneity) should be careful to consider the potentially confounding impact of sample characteristics on their findings and draw inferences with those sample characteristics in mind, particularly when comparing clinical to non-clinical groups. Second, data from the multiracial emotion identification task suggest that at least some bias related to education, race, and ethnicity can be alleviated through the use of multicultural stimuli. This notion is further supported by examining other social cognitive tasks that use multiracial/multiethnic stimuli such as the Penn Emotion Recognition Test (Gur & Gur, 2016; Kohler et al., 2003), which does not appear to be affected by participant race and ethnicity (Pinkham, Kelsven, Kouros, Harvey, & Penn, 2017). Another option would be to use stimuli that are less verbally and culturally loaded, to the extent that that is possible. The Social Attribution Task-Multiple Choice task (Bell, Fiszdon, Greig, & Wexler, 2010), for example, which involves

making judgments about non-verbal animated geometric objects acting with ostensible beliefs, desires, and intentions, has been validated for use across cultures (Lee et al., 2018). However, other research initiatives have recommended not using the task due to poor psychometric properties (Pinkham, Harvey, et al., 2017; although see Johannesen, Fiszdon, Weinstein, Ciosek, & Bell, 2018). Finally, as others have recommended (Pedraza & Mungas, 2008), new assessments should be developed and validated using more diverse samples along with statistical methods that assess whether scores have similar meanings across groups (Mungas, Reed, Crane, Haan, & González, 2004; Siedlecki, Tucker-Drob, Oishi, & Salthouse, 2008). Towards moving forward, measurement initiatives such as the Social Cognition Psychometric Evaluation study (Pinkham, Harvey, et al., 2017), will be increasingly important.

The increasing rise of large-scale cohort studies (e.g., NIH's *All of Us Research Program*), where demographic and sociocultural characteristics are likely to become increasingly crossed, means that without action towards creating sound measures, these research efforts, and others, will be profoundly undermined (Manly, 2008). Thus, we take our findings as a call to action for social cognition researchers to create measures that minimizes undue effects of sociodemographic characteristics. Given ongoing initiatives at the NIMH to select and recommend social cognitive measures for widespread use in research, the time to create and test new measures is now.

Table 1

Measure Characteristics and Hypotheses

	Characteristic			
	Mental State Understanding	Emotion Labelling	Uncommon Vocabulary	Caucasian-Only Faces
RMET	✓	✓	✓	✓
Emotion Identification	✓	✓		
Emotion Discrimination	✓			✓
Digit Symbol Matching				
	Hypothesis: If the relation between sociocultural factors and measure performance is the result of the effect described in the column heading, we would expect to see the following similarities/differences in sociocultural-performance relations...			
	Mental State Understanding Effect	Emotion Labelling Effect	Uncommon Vocabulary Effect (<i>Class Effect</i>)	Caucasian-Only Faces Effect (<i>Culture Effect</i>)
RMET	+	+	+	+
Emotion Identification	+	+	-	-
Emotion Discrimination	+	-	-	+
Digit Symbol Matching	-	-	-	-

Note. A check-mark indicates the presence of the column characteristic. Shared +/- symbols indicates that the relation between sociocultural factors and measure performance is expected to be similar if the column hypothesis is supported.

Table 2

Participant Characteristics and Task Performance

Measure	Factor	Level	<i>N</i> (%)	<i>M</i>	<i>SD</i>	Range	α

^aValues represents percentage correct.

^bValues represents number of trials correct.

Figure 1. A) Measure performance as a function of age. The red line depicts the segmented regression slopes. The vertical gray bar depicts breakpoints and their 95% CI. Data points represent mean score as function of age with error bars denoting 95% CI. B) Female>male effect sizes with 95% CI across measures. Positive values represent a female>male performance advantage; negative values represent a male>female performance advantage.

Figure 2. A) Education effects. The top panel depicts education η^2 and its 95% CI across measures. The bottom panel depicts effect size differences with 95% CI between levels of education. Positive values reflect a higher education>lower education performance advantage; negative values reflect a lower education>higher education performance advantage. Darker data points depict greater education level differences (e.g., Graduate versus Middle School); lighter data points depict smaller education level differences (e.g., Graduate versus College). Within each facet, education level differences increase from right to left. B) NIH-defined ethnicity effects. The top panel depicts ethnicity η^2 and its 95% CI across measures. The bottom panels depicts effect size differences with 95% CI between Non-Hispanic and Hispanic participants. Positive values reflect a Non-Hispanic>Hispanic performance advantage; negative values reflect a Hispanic>Non-Hispanic performance advantage. C) Race effects. The top panel depicts race η^2 and its 95% CI across measures. The bottom panels depicts effect size differences with 95% CI between European/White participants and non-European/non-White participants. Positive values reflect a European/White>non-European/non-White performance advantage; negative values reflect non-European/non-White>European/White performance advantage.
