Abstract

Purpose. Together with language, music is perhaps the most distinctive behavioral trait of the human species. Different hypotheses have been proposed to explain why only humans perform music and how this ability might have evolved in our species. *Methods.* In this paper, we advance a new model of music evolution that builds on the self-domestication view of human evolution, according to which the human phenotype is, at least in part, the outcome of a process similar to mammal domestication, triggered by the reduction in reactive aggression responses resulting from environmental changes. *Results.* In the paper, we specifically argue that self-domestication can account for some of the cognitive changes, and particularly for the behaviors conducive for the complexification of music through a cultural mechanism. We hypothesize 4 stages in the evolution of music under self-domestication forces: collective proto-music, private timbre-oriented music, small group pitch-oriented music, and finally, collective tonally-organized music. This line of development encompasses the worldwide diversity of music types and genres and parallels what has been hypothesized for languages. *Conclusion.* Overall, music diversity might have emerged in a gradual fashion under the effects of our enhanced abilities for cultural niche construction, as shaped by the progressive decrease in reactive (i.e., impulsive, triggered by fear or anger) aggression and the increase in proactive (i.e., premeditated, goal-directed) aggression.

Key words: music evolution; language evolution; self-domestication

1. INTRODUCTION

Just like language, music constitutes a distinctive behavioral trait of humans. However, current understanding of the role of music in shaping human evolution, as well as the matter of origins of music, remain far from clear - in contrast to what is known about the contribution of language (but see Wallin et al., 2000; Schulkin, 2013; Tomlinson, 2015; Perlovsky, 2017; Honing, 2019 for some hypotheses). At the same time, notable parallels exist between the structural and functional properties of music and language (see Jackendoff, 2003 for a useful review), to the extent that some authors have argued in favor of their evolutionary common origins (Harvey, 2017; Brown, 2000; see Ravignani and de Boer, 2021 for a recent critical view). In this paper, we wish to substantiate this view with a new model that heavily builds on current findings and methodologies of evolutionary linguistics. Just like the language types that emerged throughout human history as humans became more tolerant and prosocial, following a steady reduction in reactive aggression (Benítez-Burraco and Progovac, 2020), music acquired diverse typology, complexity, and functionality in its global spread.

We start this paper by overviewing the commonalities between music and language - one of the very few available sources to establish the evolutionary prehistory of music and language. Afterwards, we outline the self-domestication hypothesis (SDH) of human evolution (henceforth HSD) and explain its benefits for modeling the evolution of music and language. We finally discuss possible ways for music's interaction with language in their parallel development.

2. MUSIC AND LANGUAGE: COMMON EVOLUTIONARY ROOTS

Overall, existing hypotheses about the origins of music fall into two general classes. The first one regards music as a byproduct of the extended use of some biologically important pre-existing capacity, such as vocal signaling, sound imitation, auditory analysis, motor coordination, problem solving, and linguistic communication. The second class theories claim that music was selected because of some evolutionary advantage(s).

Music shares many commonalities with language, which also features numerous functions, typologies of complexity, and a pronounced evolutionary continuity with the cognitive and communicative abilities of other species - i.e., many characteristic traits of

human musical and linguistic communication can be traced in animal communication (see Corballis, 2020; Cowley and Kuhle, 2020; Pereira et al., 2020 for recent views).

First, quite a number of structural parameters of music - pitch, rhythm, meter, tempo, dynamics, articulation, and timbre - are also exploited by language (Besson and Schön 2001; Patel 2003; Slevc 2012; Rohrmeier et al. 2015; Heffner and Slevc 2015; Filippi et al. 2019). For example, pitch changes are used to distinguish different words in tonal languages, or different sentence types, as in prosodic intonation (see Nikolsky and Benítez-Burraco, in press, section 2.3 for ample discussion).

Second, music equals language in many of its common functions:

- 1) the *expressive* function - especially, conveying emotions (Altenmüller et al., 2013; Cook, 2002; Eerola and Vuoskoski, 2013; Gabrielsson and Juslin, 2003; Johnson-Laird and Oatley, 2010; Juslin, 2005, 2011, 2013; Krumhansl, 2002; Mohn et al., 2010; Nikolsky, 2015a; Panksepp and Trevarthen, 2009; Peretz, 2013; Perlovsky, 2012; Schiavio et al., 2016; Trainor, 2010; van Goethem and Sloboda, 2011),
- 2) the *phatic* function - i.e., reinforcing interpersonal and social bonding (D. Boer and Fischer, 2012; Clarke et al., 2015; M. Clayton, 2016; Cross, 2009; Dunbar, 2012; Harvey, 2017, 2020; Mehr et al., 2020; Savage et al., 2020; Trevarthen, 2002),
- 3) the *conative* function - i.e., calling to action (Karl and Robinson, 2015; Köhl, 2011; Leman, 2009; Liszkowski et al., 2012; Mehr et al., 2020; Monelle, 2006; Nazaikinsky, 2013; Rodman and Rodman, 2010; Tagg, 2012; Tarasti, 1998; Vuust and Roepstorff, 2008), and
- 4) the *mnemonic* function - memory conservation (Belfi et al., 2015; D. Boer and Fischer, 2012; Janata et al., 2007; Levitin, 2019; Nikolsky, 2016d; Tamm, 2019; van Dijck, 2006; Will, 2004).

Third, similar-to languages, all human cultures have developed different music systems to support important musical behaviors that fulfill specific social and psychological roles. Their form-function links remain quite stable across various cultures and societies. Although during the past 40 years, Western ethnomusicologists have leaned towards denying the global universality of specific structural patterns of pitch and rhythm organization, their stance seems to be driven by political reasons - mainly, fear of a

Eurocentric bias in conducting scientific comparative study of the world's music traditions (Blacking, 1977; Gurlay, 1984; Hood, 1977; List, 1971, 1984; Nattiez, 2012; Supičič, 1983).¹ The arguments for the non-existence of musical universalities² are all limited to the absence of specific higher-order combinatorial patterns in certain music cultures rather than to the omnipresence of certain basic principles of music-making (Brown and Jordania, 2013; Fitch, 2017; Grauer, 1996; Justus and Hutsler, 2005; Kolinski, 1978; Lomax, 1977; McAdams, 1989; Nketia, 1984; Savage et al., 2015; Tagg, 2012; Verhoef and Ravignani, 2021).

A number of common elementary “surface-level” music constructs are virtually omnipresent across the globe and rely on the perceptory mechanisms that are already active immediately after birth:

- 1) in practically every music culture, listeners recognize musical sounds as more pleasant than other types of sounds and are eager to listen to them for a long time over and over again (Alworth and Buerkle, 2013; Fitch, 2006; Granot, 2017; Hefer et al., 2009; Lots and Stone, 2008; Nieminen et al., 2011; Salimpoor and Zatorre, 2013; Schubert, 2009; Snowden, 2021; Watanabe, 2008);
- 2) listeners distinguish pleasant (consonant) from unpleasant (dissonant)³ simultaneous combinations of musical sounds and only vary in judging which specific combinations are considered “consonant” versus “dissonant” (Bidelman and Krishnan, 2009; Brandl, 2008; Cazden, 1959, 1972, 1980; Lots and Stone,

¹ Here, quite illustrative is the radical change in views of one of the leading living Western ethnomusicologists - Bruno Nettl: from postulating the need for the comparative study of cross-cultural universalities in world's music cultures (Nettl, 2000) to denial of the validity and possibility of such studies (Nettl, 2010).

² A serious miss in Western ethnomusicological publications that claim fundamental non-universality of music is that their analyses of cultural diversity zooms into the between-culture variations without much consideration for the within-culture variations that can significantly exceed the between-culture variations - quite similar to genetic diversity (Rzeszutek et al., 2012).

³ Here we have to briefly address the controversy on this issue between cognitive scientists and Western ethnomusicologists. Although the concept of consonance and dissonance have been forged within the Western civilization, their dichotomy is based on the biologically rooted mechanisms of auditory perception, present amongst not only humans but at least some animal species (Chiandetti & Vallortigara, 2011; Hulse et al., 1995; Izumi, 2000; Koda et al., 2013; Tramo et al., 2001; Watanabe et al., 2005). Consonant and dissonant combinations of tones are distinguished by means of detection of acoustic roughness and fusion of tones (Terhardt, 1974a, 1974b) - detectable soon after birth (Trainor et al., 2002; Zentner & Kagan, 1998), even for children of deaf parents (Masataka, 2006). See (Nikolsky, 2022) for the discussion.

- 2008; McPherson et al., 2020; Messner, 2006, 2013; Schellenberg and Trehub, 1996; Tenney, 1988; Terhardt, 1974b);
- 3) listeners distinguish melodic steps from leaps (Alekseyev, 1986; Bendixen et al., 2015; Bregman, 1994; Larson, 1997; Nazaikinsky, 1977, p.; Noorden, 1975; Rags, 1980; Sievers et al., 2013; Stefanics et al., 2009; Tiulin, 1937);
 - 4) regular integer-ratio rhythms from irregular rhythms (Arom, 2006; Brown and Jordania, 2013; Drake, 1998; Drake and Bertrand, 2001; Fitch, 2012; Fraisse, 1982; Jacoby et al., 2021; Monahan, 1993; Pressing, 1983; Ravignani et al., 2016);
 - 5) binary metric groups from ternary (Abecasis et al., 2005; Bergeson and Trehub, 2006; M. R. L. Clayton, 2000; Fraisse, 1982; Iyer, 1998; Jacoby et al., 2021; London, 2004; Monahan, 1993; Potter et al., 2009; Temperley, 2009);
 - 6) fast tempi from slow (Baruch and Drake, 1997; Collier and Collier, 2007; Dalla Bella et al., 2001; Ellis, 1992; Fraisse, 1982; Levitin and Cook, 1996; McAuley, 2010; Trainor et al., 2004; van Noorden and Moelants, 1999);
 - 7) experience music as virtual movement of a certain character, analogous to physical motion, but in imaginary space - formed by the alternation of tension-inducing and relaxation-inducing structures (Fraisse, 1982; Friberg and Sundberg, 1999; Iyer, 1998; Jackendoff and Lerdahl, 2006; Larson, 2012; Larson and McAdams, 2004; Larson and Vanhandel, 2005; Nazaikinsky, 1988; Nikolsky, 2015b; Rothfarb, 1988);
 - 8) use no more than 12 pitch-classes (most commonly 5-7 of different sizes) and employ logarithmic incrementation to distinguish between them within a pitch-set (Balzano, 1980; Beliaev, 1990; Brown and Jordania, 2013; Gill and Purves, 2009; Honingh and Bod, 2011; Jacoby et al., 2019; Korsakova-Kreyn, 2013; Mazel, 1952; McAdams, 1989; McBride et al., 2022; Sethares, 2005; Shepard, 2010) - which possibly shares roots with the linguistic prosody (Fenk-Oczlon, 2017; Kolinsky et al., 2009; Schwartz et al., 2003; Terhardt, 1984).

Numerous experimental studies suggest the existence of universal cross-cultural patterns of musical communication (Argstatter, 2016; Balkwill and Thompson, 1999; Egermann et al., 2015; Fritz et al., 2006, 2009; Juslin and Laukka, 2003; Kwoun, 2009; Laukka et al., 2013; Sievers et al., 2013; L. D. Smith and Williams, 1999; Stevens and Byron, 2009; Trehub et al., 1993; Yurdum et al., 2022). This line of research is extremely important in

validating claims of Western ethnomusicologists and identifying the common biomusicological foundation that underlies world's music cultures.

Fourth, newborns show innate predisposition to acquire music no less than language. Hence, there is evidence that fetuses distinguish music from environmental sounds during the last months of gestation, and newborn infants even remember music they were exposed to during the gestation (Parncutt, 2016). Acquisition of music occurs implicitly, even at the absence of formal training (Rohrmeier and Rebuschat, 2012). Infants routinely learn multiple music systems just like they learn multiple languages used by their caretakers (Wong et al., 2009). The development of musical skills in childhood seems to proceed in the direction of building new culture-specific skills of identifying culturally important conventional patterns of musical sounds (e.g., “chords” and “keys”), based on the biologically ingrained foundation of synesthetic perception of musical pitch, rhythm, timbre, and dynamics (see the discussion in (Nikolsky, 2022)). Ontogenetically, this line of development from implicit “natural” (onomatopoeic) and therefore, cross-cultural and general, to explicit “cultural” (convention-based) learning is not that different from linguistic acquisition (Berry et al., 2002; Dasen, 2012; Greenfield et al., 2003; Monaghan et al., 2014; Kidd et al. 2018; Johnson and White 2020). This emergence of "cultural" forms of musicking from "natural" forms must be responsible for the significant correlation between the geographic distribution of specific genetic variations and specific folk music traditions, as revealed by a few recent studies (Pamjav et al., 2012; Brown et al., 2014; Le Bomin et al., 2016).

Finally, music perception and production rely on specific brain circuits, resulting in distinctive, music-specific damage (i.e. amusia) when impaired (Stewart et al. 2006, Tillmann et al. 2015, Perrone-Capano 2017, Reybrouck et al. 2018, Vuust et al. 2022). This substrate shows extensive overlapping with the substrate of language, specifically in syntax processing (Brown et al. 2006, Harvey, 2017; Sun et al. 2018, Asano, 2021; but see Chen et al., 2021 for an opposite view).

Overall, pretty much as one can argue for a human *linguisticity* - i.e., the set of capacities that allow humans to learn and use languages in all their diverse forms (after Haspelmath, 2020) - one can argue for a human *musicality*, understood as an innate predisposition to perceive and create music, encompassing all the perceptual, cognitive, and behavioral

aspects of music. Our contention here is that these parallels can be also extended to the evolutionary domain. Retaining the parallel with language(s) again, in no way music should be regarded as a recent cultural invention⁴. Musicality must be an ancient capacity that has manifested in different types of music along the long pathway of *Homo sapiens*, reflecting the milestones in its cultural evolution, as well as important cognitive and behavioral changes.

In view of the similarities reviewed above, some scholars (most notably, Brown, 2000) have suggested that language and music might share common evolutionary roots. However, as noted by Cross and colleagues (2013), even this being the case, there are a few likely scenarios of their emergence: music developing from language (Spencer's view), language emerging from music (Darwin's view), or language and music splitting up from a common *musilanguage* (Brown's view), and afterwards following different, but still related (and perhaps interacting) trajectories (Harvey, 2020). In this paper, we propose a new model of the evolution of music that adheres to the latter possibility.

3. WHAT MUSIC FUNCTIONS CAN TELL ABOUT THE EVOLUTION OF MUSIC

Pretty much as for language, one can think of diverse functions for which music might have been selected – and even estimate a timeline for the selection of each type of function. Most of the functions of music mentioned in the previous section can be characterized as “external” to the subject and thus execute some social role: e.g., the establishment and consolidation of social bonds within human groups (Dunbar, 2012a, 2012b; Harvey, 2017; 2018; Savage et al., 2020), the conveyance of credible information to others, either for signaling mate quality (e.g. Merker 2000, Miller 2000), or for coping with progressively complex social conflicts of interest (Mehr et al., 2020). Nonetheless, an “internal” role for music has been hypothesized as well, e.g., Perlovsky's (2017) view of music as a tool for overcoming unpleasant emotions, resulting from our interaction with the environment. Often, “external” functions of music, most notably those related to social bonding, impact the “internal” state of a subject by influencing the stress-response systems or the rewards systems (see Dunbar, 2012a,b; Harvey, 2020; Savage et al., 2020

⁴ By cultural invention we mean a new set of behavior adopted by a group of people and passed on to others within that group as well as outside of it.

for discussion). Accordingly, it is not an easy task to infer an evolutionary path for these functions.

A promising approach is to cross-examine the co-dependencies between the most common music functions, based on the music skills required to process those music structures that characterize each of these functions.⁵ Like language, music is structurally determined by the functions it regularly performs. Once forged, such structures, in turn, start supporting and conserving a function that shaped them.⁶ As a result, these formative functions form complex dependencies, where one function cannot operate without another function being accessible.⁷ More importantly, some functions build the foundation for others, supporting new modes of interaction with the physical and particularly, the cultural environment.

In our recent paper (Nikolsky and Benítez-Burraco, in press), we presented a thorough reconstruction of the entire chain of dependencies of the most common formative music functions - tracking them down to the primordial hedonistic function that underlies all

⁵ This approach follows the “central neoformation” model, proposed by Vygotsky to describe and explain the general cognitive development (ontogenetic and phylogenetic) and further elaborated by his school: Alexander Luria, Aleksey Leontyev, Piotr Galperin, Daniil Elkonin, and Aleksander Zaporozhets, who headed a lab that researched music perception (Zaporozhets, 1985) (see the discussion in (Nikolsky, 2022)). According to this model (van der Veer & Valsiner, 1991; Vygotsky, 1987, 2013), each developmental period is forged by the necessity to master a new cognitive function that is imperative for handling critical environmental challenges. Vygotsky called it “central function” because, once established, it remains stable throughout the entire period, laying the foundation for the neoformation of the next stage. This way, the entire line of development becomes cumulative and modular. Each progressive period is characterized by the increase of cultural diversity in implementation of each central neoformation.

⁶ Thus, “Physical aid” function relies on the presence of rhythmic idioms embedded in a metric grid and sustained in a tempo range suitable for accompanying specific physical activities (e.g., walking for marches or lulling for lullabies). Once forged, such idioms start conserving the compositional arrangement of music that supports the same character of movement - e.g., all march-like music within the same musical culture shares the same metro-rhythmic design within the same tempo range, whether this music belongs to a genre of march or is a part of some other genre, such as symphony, opera, ballet, suite, song, sonata, or concerto.

⁷ For example, “Emotional regulation” requires the functions of “Emotional communication”, “Interpersonal bonding”, and “Physical aid” to be already established. To successfully choose music to change or “lock in” a specific emotional state, one must know that music can communicate musical emotions, that these emotions can bring participants to share the same emotional state and thereby bond together, and to realize that the presence of specific structural patterns in music can match or mismatch certain activities. In turn, “Emotional regulation” function must be available in order for “Compliance to norms” to emerge.

others. We identified in the recent research literature 14 operational functions⁸ (Bispham, 2018; D. Boer and Fischer, 2012; Brown, 2005; M. Clayton, 2016; Dissanayake, 2005; Levitin, 2019; Perlovsky, 2014; Savage et al., 2015; Schäfer et al., 2012; Schäfer and Sedlmeier, 2009; Stefanija, 2007; Trevarthen, 2009; van Goethem and Sloboda, 2011):

- ***hedonistic stimulation*** (make music or listen to it to experience pleasure),
- ***emotional communication*** (make or listen to music that expresses one's current emotional state or characterizes a state of a third party),
- ***emotional regulation*** (make or listen to a selected type of music to maintain a desired emotional state or to change an undesired one),
- ***compliance to norms*** (ritualizing one's behavior and organizing one's feelings and goals in accordance with some ideal, collective task, or belief),
- ***recreation*** (entertain an individual or/and a social group by doing something not totally predictable, such as improvising, exploring a new instrument, or playing singing/vocalization games),
- ***interpersonal bonding*** (secure close relations with another individual or a social group by sharing a musical experience with them),
- ***coalition status display*** (publicly display one's membership in a specific social group or project and affirm a wish-to-be social identity),
- ***physical aid*** (support a specific pattern of physical motion in one's daily work, play, or workout, collective or solitary),
- ***learning aid*** (stimulate the discovery of new things and help remember important information, as in children's learning songs),
- ***contemplating an event*** (evoke the imagery of an important occasion, holiday, season, sporting event, place of interest, landmark, or monument),
- ***calling to action*** (music signaling, as in military bugle signals or herding calls - i.e., supporting language-like commands - and the creative use of such semiosis to entertain the audience, as in "programme music"),

⁸ There are many more music functions that have been identified in literature on music. However, we were interested only in those functions whose existence was experimentally confirmed, reported in numerous music cultures, secured by a well-established tradition of production and/or consumption, and characterized by objectively recognizable structural features. We did our best to get rid of redundancies and minor variations in functionality by grouping similar functions into a single type according to the common mental operation(s) they require. So, our list presents 14 basic operational types to illustrate this novel method of inquiry into the evolution of music. Other researchers are welcome to improve it.

- ***conservation of memories*** (preserve a valuable memory for an individual and his/her closest people, usually nostalgic, and maintain one's mental integrity under pressure),
- ***self-promotion*** (exhibit one's music faculties to increase confidence, self-esteem, and/or earn respect or show superiority),
- ***personal profiting*** (earn money and/or fame by making music as a professional occupation).

We cannot dedicate much space to the discussion of these functions here and will only cover those points that directly relate to the evolution of music and language.

Figure 1 below summarizes the co-dependencies that we have established in our 2022 paper. “Hedonistic stimulation” does not depend on any other function and is not only cross-cultural but cross-specific for a number of non-human species. Therefore, it is placed at the root. “Personal profiting” and “Calling to action” do not support other functions. Therefore, they go to the top. Other functions are distributed in-between according to their dependencies.⁹

Noteworthy, the lower-order functions form the succession that fits the pattern of acquisition of musical skills throughout childhood (see the discussion in Nikolsky, 2022). “*Hedonistic stimulation*” by music seems to be inborn and universal. It supports and enables the acquisition of every other music function. “*Learning aid*” capitalizes on the capacity of music to bring pleasure, connecting it to the disposition to learn new things and the mnemonic power of music (evident in the earworm phenomenon and the efficacy of music therapy in treating dementia). Multimodal interaction with the mothering figure, whose singing, motherese, touch, movements, and gestures altogether shape this “learning” function, teaching an infant the principles of communication. “*Interpersonal bonding*” emerges from the ongoing communication with caretakers, usually set by the mother and thereafter expanded to other close relatives. Based on the observed patterns

⁹ Of course, it is hard to define the operational dependencies for each of the musical functions, established in the literature. Arguments for their tentative order in Figure 1 are presented in Nikolsky and Benítez-Burraco, in press. The ultimate ordering requires thorough experimental research. The connection of operational functions with specific musical genres, outlined in the above-mentioned paper, and with those musical structures that characterize such genres will allow researchers to test, how exactly various types of listeners perceive music that specializes on each of the musical functions.

of vocal communication, throughout the 2nd year of life, infants engage in active musicking - in the form of solitary musical babbling that introduces the “*Recreation*” function. However, musical babbling remains very similar to verbal babbling. All of these 4 basic functions are engaged in verbal acquisition too.

Figure-1. Evolutionary development of operational functions of music. 14 operational functions are placed along 2 axes: temporal (vertical) and social (horizontal). The former (on the left, in pink) reflects the operational dependencies between all functions, which is generally representative of the ontogenetic pattern of acquisition of music skills throughout childhood. On the right (in purple), the corresponding phylogenetic line of development is outlined. The horizontal axis shows the gradual social expansion in the use of functions throughout childhood. The ellipsis after the name of a function indicates that this function keeps developing towards engaging a greater number of participants - the extent of which is reflected by the relative length of the surrounding box after the ellipsis. Black arrows show the derivative relations between functions. A blue rectangle at the bottom encloses functions that are undifferentiated from verbal communication and

characteristic for the “musilanguage”. A green rectangle marks the functions that are differentiated from verbal communication but are not autonomous from it, representative of proto-music and earliest forms of “personal music.” Darker green color distinguishes more biologically dependent functions from more culturally varied ones. A yellow rectangle encloses functions specific to music. Darker yellow color distinguishes functions based on informal, orally transmitted, and implicit musical grammars from formally-learned, notation-based, and explicit grammars.

Hours of dedicated exercising self-initiated vocalizations, accompanied by spontaneous physical movements, lead to discovery of the expressive capacities of melodic leaps, steps, directionality, dynamics, and, eventually, rhythm and tempo. Infants learn melodic movement as they learn physical movement. Mastering melodic leaps and steps accompanies learning to walk. Thereby, music evolves into the “*Physical aid*” function. Through solitary exploration of singing while moving, playing with toys, drawing, etc., children discover that certain types of melodic motion suit certain types of physical motion. Specific musical patterns become associated with the affective characteristics of the accompanying locomotion and with the imaginary characters of toys and protagonists of drawings. From this point on, musical expression focuses on “*Emotional communication*,” while verbal expression - on referential. However, both keep sharing the same functions: like music, speech conveys emotions, accompanies locomotion in play-games, and entertains (tongue-twisters, nurseries).

Music expression becomes autonomous from speech, once children start using skills they have learned in emotional communication to control their emotional state: avoid negative emotions, bring themselves into a state required by a social situation, etc.. “*Emotional regulation*” opens doors to “*Compliance to norms*” - children start learning ritual behaviors for different environmental settings. Music comes handy in organizing “rituals” for collective activities (worksongs, playsongs, anthems, hymns, theme songs). As such activities keep expanding the number of participants and increasing the distance of musical communication beyond the intimate space (typical for motherese), tonal organization of music starts obtaining pitch orientation (see Nikolsky and Benítez-Burraco, in press for details). The emerging pitch patterns become more and more culture-specific - averaging the knowledge and preferences of the growing pool of participants in musicking.

Variety of learned musical rituals enable one to display their “*Coalition status*” - i.e., to demonstrate which norms one chooses to abide by to a growing number of other people, thereby using music preferences as a social “identity badge.” This function is exceedingly important amongst teenagers, laying the ground for another function, very important for adults - “*Conservation of memories*.” Music, patronized in youth, is usually cherished throughout life and serves to maintain one’s integrity. The latter, in turn, becomes indispensable for “*Self-promotion*”. Rising one’s self-esteem and earning respect through performance and patronization of sophisticated music requires stylistic consistency and adherence to the earlier established values.

“*Self-promotion*” can evolve into “*Personal profiting*” for those who achieve technical proficiency and artistic integrity in music.¹⁰ In modern societies, where music schooling supports music notation, reproduction, and wide distribution of music compositions, this option might be quite lucrative - in contrast to folk music cultures, where active musicking constitutes the norm. Similarly, notation and formal schooling facilitates accumulation of knowledge and acquisition of basic arranging skills, especially valuable for the evolution of “*Conservation of memories*” into “*Contemplating an event*”. The latter supports the capacity to use music in reference to specific circumstances in their absence from the immediate environment (e.g., contemplating Christmas by listening, playing, or imagining the sound of carols during summer). Building a lexicon of music idioms to refer to many culturally important events (including foreign and exotic) leads to the acquisition of the most advanced musical function - “*Calling to action*.” It supports the capacity to suggest affective states, characters, imagery, and attitudes by choosing and arranging suitable music structures and convincingly rendering them for the audience. This function is almost entirely based on cultural conventions and learning.

4. PHYLOGENY MEETS ONTOGENY

¹⁰ Attaining expertise in Western music cultures is usually confined to performance (e.g., composers, improvisers, and interpreters of pre-existing music), but sometimes occurs in applications related to listening and appreciation of music (e.g., music critics, reviewers, competition jurors, programmers, DJs, radio hosts, sound designers, etc.). In any case, connoisseurship in music allows one to monetize their music skills one way or another. However, this opportunity is available for relatively few specially gifted individuals and demands much time, effort, and, usually, some luck.

This entire line of *ontogenetic* musical development finds a close match in *phylogenetic* development - after all, a cultural phenomenon can exist in no other way but through the successful transfer from one generation to another in quantities, sufficient for its survival. The success is largely determined by the psychophysiological limitations of a learning youngster and the ability of adult experts to cater to that person (see (Nikolsky, 2020a) for thorough discussion). Hence, the infantile functions correspond to the musilanguage stage in the evolution of music and language. Both are characterized by the prevalence of personal and duetic settings - epitomized in, respectively, babbling and motherese. Presence of a diverse repertory of relatively well-structured signals, adopted as a standard to convey certain types of information, must have distinguished human musilanguage from animal communication. Longer altriciality and ever-growing capacity to accumulate knowledge must have promoted this diversification. The typical forms of preverbal interactions between infant and caregiver provide at least some idea of how the musilanguage systems might have been put into use by humans before the emergence of modern articulate speech and true human musicality (Harvey 2017).

Differentiation of musical and verbal acquisition during the age of 3-5 years corresponds to the divergence of “proto-music” and “proto-language”. Their mutual cut-off from the preceding musilanguage probably occurred due to discovery and appreciation of singing and metro-rhythm (likely discovered through the entrained knapping during collective manufacturing of stone tools). This stage can be characterized by crystallization of *proto-genres*¹¹ - i.e., forms of musicking developed to accompany collective hunting and

¹¹ Musicking that occurs within motherese, grunting during grooming, humming during leisure time, or personal songs should not be considered “musical genres.” Musical genre is a specific type of music, distinguished by similarity of musical structures, semantic content, usage, and manner of expression within a community of music-users (see (Fabbri et al., 1982; Kallberg, 1988; Korobova, 2007; Lobanova, 2013; Nazaikinsky, 2013; Samson, 2001; Samuels, 2004; Sokhor, 1968, 1971; Tsaryova, 1976; Tsukkerman, 1964). Thus, lullabies can be identified by their ongoing repetitions of brief motivic formulas that contain soft descending 2nds and minor 3rds in slow tempo, applicable to lulling. Most lullabies share such features and therefore can be recognized even when they are arranged for different performance settings, such as symphonic orchestra. Equally recognizable are the semantic characteristics of lullabies - they are distinguished by general relaxation of the listeners, probably due to the influence of the music structures associated with gentle rocking at the regular sustained pace. This relaxing effect was found even in infants who responded to unfamiliar foreign lullabies (Bainbridge, 2021). Musical genres are extremely important for the generation of musical idioms. However, motherese or personal songs fall short of constituting a “genre” - its typology is too diffused and individualized to “canonize” a specific set of expressive means capable of characterizing a particular topic. For this reason, we prefer to qualify the structural and semantic uniformity of specific applications of proto-music as “proto-genres”.

repelling of predators or personal caretaking, such as mothering and grooming. The phylogenetic equivalent of the formation of a mother-child “microcosm” (and its further expansion into a “macrocosm” of friends and acquaintances) would be the emergence of a family nucleus and significant reduction of aggression within it amongst early humans (followed by the expansion of this nucleus). The direct connection between the increase in attachment behaviors, so instrumental for the evolution of language and music, and hormonal effects of the peptide oxytocin on music-related activities was thoroughly discussed by Harvey (2020).

The next phase of ontogenetic development - learning to express musical emotions and to use them to optimize one’s state - marks the onset of a new phylogenetic stage of “proto-music” turning into “music”, fueled by the emergence of *musical mode*. The latter can be defined as a social convention for combining certain types of musical sounds into sets for expression of a particular topic. Musical modes are inseparable from musical genres: in virtually every folk music culture, each basic genre¹² (e.g., lullaby) supplies one or a few characteristic musical modes (so that all applications of the same genre sound recognizably the same).

In case of timbre-oriented music, musical modes are timbral - they join not pitch-classes but “timbre-classes” (as in Jaw Harp music - see (Nikolsky et al., 2020)). Timbre-matching has been reported in mother-infant communication (Malloch, 2000, 2004), driven by the instinct to adjust one’s vocalizations to those of an interlocutor. The emergence of this capacity likely occurred some time in the late Paleolithic and marked the birth of timbral music from proto-music.

The next evolutionary advance was the conversion of timbre-classes into pitch-classes and transition from timbre- to pitch-orientation. Ontogenetically, this transition usually occurs at the age of 3-5 years through the practice of “objectivization” of pitch values in music, when salient pitch changes become associated with physical objects, qualities, and events based on the synaesthetic connections between melodic motion and physical

¹² A musical genre can be considered “basic” if it cannot encompass another genre and is directly used by the majority of population within a music culture in folk transmission (Korobova, 2007; Lobanova, 2013; Nazaikinsky, 2013; Tsukkerman, 1964). Genres that “house” smaller genres (e.g., opera) can be considered “complex.” Usually, they emerge in societies that use music notation, formal music theory, and professionalized forms of music.

motion observed by children in their environment (see (Nikolsky, 2022))¹³. The other important factors contributing to the emergence of pitch orientation are:

- 1) long chains of folk-style person-to-person transmission (see Chapter-5 in (Nikolsky and Benítez-Burraco, in press)),
- 2) spread of collective singing with the accompaniment of rhythmic and melodic musical instruments (Morley, 2013),
- 3) concentration of people in a confined space of caves that became the preferred form of shelter towards the end of the Paleolithic (the reverberation converts melodic intervals into harmonic intervals by prolonging the “tails” of preceding melodic tones (Nikolsky and Benítez-Burraco, in press),
- 4) musicking at distances where listeners cannot discriminate between different timbre-classes, especially if the distance changes during the same session of musical communication (as in herding - see (Nikolsky, 2020b)).

The 5th phase of musical ontogenesis corresponds to the evolutionary stage, when musical keys emerged from musical modes (first documented in Ancient Greece - see (Nikolsky, 2016c)), eventually forming “tonality” that came to replace “modality” (Nikolsky and Benítez-Burraco, in press). In short, this stage is characterized by the adoption of standardized tuning, as defined by the practice of tuning musical instruments most important for a given musical culture. Musical keys “canonize” specific sets of pitch-classes, convenient for playing on the preferred musical instruments. Such sets become adopted for other musical instruments and vocals within the same music culture through the practice of mixed ensemble performance. With the advance of ensemble music and rise of formal music theory, a culture establishes an assortment of keys for conventional forms of expression across all the important genres - generating a “tonality”, i.e. a system of keys (in other words, a *set of sets* of pitch-classes). Western classical tonality constitutes just one particular case of tonality. Indian *raga*, Arabic *maqam*,

¹³ Objectivization of music and the resulting qualitative change in discrimination of pitch from timbre-based to frequency-based was demonstrated in series of experiments conducted by Zaporozhets and his research group (Endovitskaya, 1964; Lisina, 1966; Mukhina & Lisina, 1966; Repina, 1966; Zaporozhets, 1985) and by Leontyev (Leontyev, 2009), as well as in the earlier research by Teplov (Teplov, 1947). Their model of gradual transformation of the timbre-oriented “verbal hearing” into the pitch-oriented “musical hearing” was confirmed in numerous methodological studies of early music education (which was obligatory in the USSR, and therefore studied on a sample pool of millions of people), systematically conducted and reviewed from the late 1920s onwards (see Nikolsky 2022).

Persian *dastgah*, or Chinese *yuye* each implement “tonality” in their own way, according to their cultural values.

If the musilanguage and proto-music stages are characterized by cross-cultural uniformity, since they rely mostly on the innate forms of encoding information into auditory signals (what we call *anthropophonic* and *onomatopoeic* intonation types), the tonality stage exhibits maximal cultural diversity and minimal universality of the musical expressive means. That is, the task of comprehending music created within a tonality system absolutely requires a listener to learn the conventions of the corresponding music culture. In contrast, comprehension of the earliest forms of tonal organization of music can rely on the biomusicological universalities and synesthetic associations. The challenge of conducting a comparative study of music (synchronic and diachronic) is that each musical function, once established, remains accessible, supporting the higher order functions, while becoming adjusted to the broader user-base. Functions, as well as music genres and traditions that rely on such genres, do not become replaced by newer functions, genres, and traditions - but add up, disappearing only after a prolonged absence of any use.¹⁴

For example, the foundation for “*Physical aid*” function is prepared by the mother moving the infant's limbs to her motherese talking and singing. Embodied in this way, sound patterns are further explored by a child during sessions of solitary babbling, accompanied with spontaneous self-induced locomotion. The discovered correspondences between melodic and physical motion are further explored in singing that accompanies solitary playing with dolls, toys, and in drawing - where each character receives a dedicated musical pattern. Such games start involving playmates and including nurseries, ditties, and popular songs, re-arranged for each instance of application. As children learn the assortment of patterns of various musical movements, they can participate in work-songs and other music-based activities together with adults (which is exceedingly common in traditional societies). In modern urban culture, teenage children rapidly advance to the stage of mass consumption of music - they switch from active performance to passive listening and learn to select music for background listening while doing something (e.g.,

¹⁴ The ontogenetic model for this is known as “attrition of music skills” - see (Nikolsky, 2020b). An equivalent phylogenetic model can be conceived along the same lines.

jogging or weight-lifting). This way, the initially personal use of melodic motion ends up expanding to involve thousands of participants (e.g., a session of rhythmic gymnastics streamed over the internet) as the “Physical aid” function passes through developmental rounds with a broadening user-base. Similar development must have taken place in cultural evolution of music as human societies grew in size and complexity, and music was put into serving a greater number of users.

The most important take from the variability of musical functions and their cumulative nature is that any analysis and comparison of music should involve the entirety of relevant musical functions, their structural implementation, and the numerosity of their users.

5. THE FORMATIVE POWER OF CULTURAL TRANSMISSION ON MUSIC AND LANGUAGE

To add a final piece to the evolutionary puzzle, we have to point out that cultural transmission per se exerts a formative power over music structures - just like verbal structures are shaped by transmission chains. Thus, Lumaca and Baggio (2017) experimentally demonstrated how transmission altered pitch and rhythm aspects of the transmitted pattern, resulting in *diatonization* of the initial model - i.e., *chromatic* semitones being systematically replaced by *diatonic* whole tones, thereby increasing music’s compliance to conventional keys. The formative power of transmission goes as far as to transform *ekmelic* intonations - i.e., gradual changes in pitch and indefinite pitch values (like pitch contours of spoken sentences) - into *emmelic* intonations (incremental changes in pitch with definite pitch values) at the end of a transmission chain (Verhoef, 2012, Verhoef et al. 2014).

Discretization and diatonization seem to occur, because the transmitter tends to complicate a specific pattern in an attempt to increase its expressivity, whereas the receiver tends to simplify it in sake of easier learning (Kirby et al., 2015). This trade-off eventually results in the increased compressibility of the encoding and the regularization of the variables. The longer the transmission chain, the stronger the effect. Iterated learning generates natural selection for optimal acoustic distinctiveness, supporting the transformation of non-combinatorial signals into combinatorial (Zuidema and de Boer, 2009). The same process is at work in linguistic and musical transmissions: each receiver intuitively strives to minimize entropy while learning a structure, which promotes compression of information and the emergence of compression regularities, thereby

generating grammars (Tamariz and Kirby, 2016). Here, yet another peculiarity of transmission comes into play - every new learner tends to uniform those structures that just slightly differ (Smith and Wonnacott 2009). This leads to crystallization of grammatical rules.

Music has been denied having grammar, meaning, and compositionality by quite a number of scholars. The reasons for this are numerous:

- confusion over the typology of music functions and uses,
- disregard for music structures and analysis of music form, common amongst Western ethnomusicologists,
- absence of general definition of music and disinterest in coining it,
- demise of comparative ethnomusicology in the West after WWII for political reasons, and
- a pronounced Eurocentric bias amongst many Western cognitive scientists and developmental psychologists who hold Western classical music for the universal model of tonal organization.

Nonetheless, what tells music apart from other auditory phenomena, we believe, is music's overall orientation toward putting the listener in a specific pre-mediated emotional state and keeping them in that state for an extended period of time - and doing this repeatedly, so that the same type of sonic material becomes associated with a specific type of semantic content by means of public convention (see (Nikolsky, 2015a, 2020b; Nikolsky and Benítez-Burraco, in press)¹⁵. We realize that the idea of tying the concept of music to emotion appears unattractive to many scholars with a background in classical music composition, performance, and music history - ever since Stravinsky and post-WWII avant-garde won critical acclaim in Western academia and amongst prestigious cultural philanthropic organizations.¹⁶ However, any attempt to tweak the general

¹⁵ It is worth noting that music allows an individual to experience a specific emotional state and share it with others in a collective performance, thereby supporting emotional interaction even in a situation where each participant may have very different outlooks and goals - what Ian Cross (e.g. 2009) regarded as provision of "safe space" expression for each individual.

¹⁶ The modernistic and post-modernistic Western anti-emotional stance should be regarded as a peculiar manneristic episode in the millennia-long history of world's music (at least from ca. 40 kya). And even within this narrow uniquely Western historic period, anti-emotionalism is fractional: all commercially viable forms of music still keep engaging musical emotions, and even Western avant-garde music also has contained styles clearly affiliated with deliberate emotional

definition of music in order to incorporate the latest century-long development of just one music tradition (albeit a very important one) is methodologically wrong (generalizing on a sample size of one). We cannot name a single non-Western musical tradition that abstains from using musical emotions and musical genres (which usually serve to assign affective qualia to specific music structures, generating convention-based semiosis in music).¹⁷

Morphologically, music closely follows language in employing both combinatoriality and compositionality, although, as noted above, there is some controversy as to whether music syntax is processed in the same cortical regions as language syntax. Music combines many *meaningless* elementary units - pitch-, rhythm- and timbre-classes, metric beats, and voices in texture - to generate *meaningful* morpho-syntactic units, such as motifs, chords, rhythmic figures, metric groups, and textural components (e.g., accompaniment, counter-melody, pedal tone) that carry certain semantic values (e.g., sighing motif, sad chord, bouncing rhythmic figure, leisurely swaying ternary meter, stiffening pedal tone, etc.). These morpho-syntactic units are conjoined according to a set of rules that distinguish each musical tradition, enabling listeners to identify a tradition by ear (Nazaikinsky, 1982). For instance, in Gregorian plainchant, melodic leaps, regular meters, the so-called “dotted” (aka “punctured”) rhythms, chords, and chromatic alterations are to be avoided altogether (Ferreira, 1997), whereas in Western military march music, they are encouraged (Monelle, 2006). Mastering such traditions requires apprenticeship, so that a layperson would learn their compositional principles.

expression and traditional genres (e.g., pre-WWII, Bartok and Berg as opposed to Stravinsky, and post-WWII, Nono, Lutoslawski, and Schnittke as opposed to Boulez, Xenakis, and Stockhausen).

¹⁷ On the other hand, attempts to omit the issue of musical emotions and define music in a most general way as “a creative play with sound” (e.g., (Brandt et al., 2022)) seems insufficient - not tested by falsification. Many forms of poetry, including traditional folk epic and lyric genres, also feature what can be called “creative play” with phonetic (i.e., timbral), rhythm-metric, dynamic, and prosodic aspects of linguistic expression, all of which are shared with music. Furthermore, if poetry can be argued to constitute an intentionally “musicalized” use of language, some sounds that by design clearly have nothing to do with music satisfy this definition. At the extreme, car manufacturers design engine noises to excite or please the driver while distinguishing between different operational modes (e.g. starting the engine, speeding up, changing gears, etc.). For example, see: <https://www.volkswagenag.com/en/news/stories/2019/03/volkswagen-sound-design.html>

Western, Arabic, Persian, Indian, and Chinese classical music traditions each feature hundreds if not thousands of treatises on music composition.¹⁸ Western compositional music theory is rooted in the Ancient Greek theory of rhetoric, understood as the craft and science of bringing the audience into a specific emotional disposition (Bartel, 1997; Bonds, 1991; Harrison, 1990; Kallberg, 1988; Keller, 1973; Mabbett, 1990; Meier, 1990; Vickers, 1984; Zakharova, 1983).¹⁹ The musical implementation of rhetoric occurred initially through the liturgic practice of composing sermons and supporting the verses required for liturgy with music (Murphy, 1981), but by the 18th century the theory of musical rhetoric firmly held its ground in purely instrumental and secular forms of music (see (Mattheson and Harriss, 1981)). Other musical cultures featured their own pathways of developing musical rhetoric (see (Dorchak, 2016; López-Cano, 2020; Powers, 1980; Rink, 1989; A. L. Smith, 1971; Theodosopoulou, 2019), including such a recent development as composing music for advertising (Scott, 1990).

Chain transmissions inherently introduce and magnify cultural biases in music structures and combinatorial and compositional rules, since different cultures favor different structural features in response to culturally-dependent factors, such as popularity, social prestige, and the likes of them. The same applies to the domain of speech (Verhoef et al., 2014). More generally, experiments involving artificial languages suggest that the cultural transmission of linguistic structures promotes compressible regularities, combinatorial rules, and compositionality (Kirby et al., 2015; Tamariz and Kirby, 2016). The analysis of sign languages, spontaneously developed by isolated deaf populations, also suggests that some basic properties of language (like duality of pattern) are lacking at the beginning of transmission and emerge gradually as a result of increased interactions between signers (Sandler et al., 2005; Dachkovsky et al., 2018).

¹⁸ The compositionality of music becomes evident whenever the same tune is used in different musical traditions - the very same motifs and rhythms receive different arrangements according to different compositional principles. Such are the compositions by a Polish prisoner of war, Wojciech Bobowski (1610-1675), aka Ali Ufki, from his treatise “*Mecmua-yi saz ü söz*” [Collection of instrumental and vocal pieces], re-arranged according to the homophonic principles by Dimitrius Cantemir (1683-1723), a Moldavian prince, in his treatise “*Kitāb-i ‘ilmü ‘l mūzīkī ‘ala Vechi’l-Hurufar*” [“Book on the science of music”].

¹⁹ All standard music forms that are commonly used today one way or another descend from the theory of music rhetoric as it has been elaborated throughout the 16-18th centuries before Adolf Marx standardized the most common schemes of arranging themes and their development in the beginning of the 19th century (Bonds, 1991; Marx & Burnham, 1997; Moyer, 1969). Thus, the treatment of rhetorical canons - *prooemium*, *divisio*, *confirmatio*, *confutatio*, *peroratio* - in the domain of music became embedded in the so-called “sonata form” (ibid.).

It is true that in the case of music, it is more difficult to identify “idiomatic” structures (i.e., music lexicons of specific music-user communities) and combinatorial rules (i.e., conventional music grammars). The reason for this might be the growing prevalence of “tree-like” transmission - i.e., chain-like passing of a music work from a person to a group (Nettl, 2005)²⁰. “Tree-like” transmission tends to replace folk-style “linear” person-to-person transmission as notation, formal music theory, and professional forms of public performance start obtaining greater share in a musical culture. Notation and theory substantially aid learning, thereby reducing the formative power of simplification in learning on part of the listeners throughout the transmission chain.

The presence of an audience, in turn, incentivizes performers to intuitively amplify their expression in order to increase the rhetorical control over the listeners. As a result, the innovation rate in exploring newer expressive means grows - structural patterns are modified more at every new act of transmission. Subsequently, the diversity of the emerging variants increases, since each of the multiple listeners inevitably introduces slight variations in the learned music, when they pass it on to new listeners. The compound effect of the “tree-like” transmission greatly exceeds that of “linear” transmission. Prevalence of “linear” transmission makes music cultures that remain primarily “personal” in their music usage to stand out as amazingly conservative in comparison to music cultures that primarily employ collective forms of performance and listening. The greater the number of the ensemble performers typical for a given tradition (e.g., orchestral music) and the size of its audience (e.g., concert hall, radio), the higher the innovation rate (Alekseyev, 1976, 1986, 1988). Naturally, the greater the discrepancy between synchronic and diachronic invariants of the same musical structure, the vaguer its structural and semantic characteristics and the weaker combinatorial rules of its use. Language does not have this problem, because in everyday use, “person-to-person” distribution remains prevalent over “person-to-group” (for the discussion of harmonization versus individualization see Harvey 2017).

²⁰ Here we have to note the similarity between the transmission of specific music structures and the genetic transmission in light of general similarity between variation in genetics and variations in music styles (Pamjav et al., 2012; Brown et al., 2014; Le Bomin et al., 2016).

Music is more oriented to the expression, transmission, and *prolonged* experience of emotions, whereas language is more optimized for delivering *prompt* referential information. Therefore, oral verbal encoding is designed for quick peer-to-peer streaming, where information has to be constantly chunked by parsing the stream of sounds, identifying words in it, retrieving their meanings, interpreting phrases, and constructing the meaning in a cumulative way. All of this relies on clarity of phonemic and morphological contrasts, while prioritizing the processing speed and robust error-correction.

Conversely, music is designed to impart particular musical emotions and to produce specific affected states in the listener where the listener as though “lives through” the music and has enough time to experience such a state.

- This requirement slows down music’s transmission rates, giving music a meditative appearance,
- causes music to simultaneously engage multiple aspects of expression, each with its own proprietary “idiomatic” patterns (rhythmic, metric, melodic, harmonic, etc.), and
- grounds music to iconic semiosis and synesthetic correspondences between the musical meaning and the acoustic attributes of music sounds.

This distinction between music and language is far from being clear-cut. Language also conveys emotional contents and is partially iconic - especially poetic speech, where iconicity facilitates word learning and communication, while systematicity facilitates category learning. Linguistic arbitrariness, iconicity, and systematicity interact in complex ways under the effects of cultural selection to reshape not only a language’s vocabulary, but also its grammar, promoting compositionality and regularity (Dingemanse et al., 2015). Nevertheless, the differences between musical and linguistic oral transmissions are sufficient to make music functions form operational relations quite different from language functions. Notably, music functions rely on each other to such an extent that higher-order functions can hardly be fully operational without lower-order functions being effectively engaged.

Subsequently, the study of evolution of music requires the consideration of all music functions in their systemic relations. Most disagreements between extant theories of the

evolution of music seem to originate from the limitation of study to only a few functions, specific to the earliest or latest stages of evolutionary development, while ignoring the other functions. Moreover, both biological and cultural factors need to be considered on par and in their interaction.

6. HUMAN SELF-DOMESTICATION AND LANGUAGE EVOLUTION

In the next two sections we present a model of music evolution to account for musical functions and for biological and cultural factors formative for music structure and function. Our model is based on a recent account of human evolution, namely, the hypothesis of “human self-domestication” (HSD), which has been successfully applied to the characterization of language evolution in our species (Thomas and Kirby, 2018; Benítez-Burraco and Progovac, 2020). Because of the parallels between music and language discussed above, we expect this evolutionary model to be applicable to music.

The HSD hypothesis supports the view that human phenotype is, to a large extent, the outcome of an evolutionary process similar to animal domestication. In mammals, domestication initially involved selection for tameness and resulted in a set of distinctive traits - physical, cognitive, and behavioral - that usually co-occurred, forming the so-called *domestication syndrome* (Wilkins et al., 2014, see Sanchez-Villagra et al., 2019, Lord et al., 2020 for critical views). This might be due to the fact that tameness reduces the input to the neural crest - i.e., an embryonic structure that supports the ontogenetic development of numerous body parts (see Wilkins et al., 2014; see Sánchez-Villagra et al., 2016, Lord et al., 2020). The HSD hypothesis builds on the findings of many domestication traits in humans. This includes smaller skulls/brains (as compared to archaic humans); reduced hair; neotenic features (e.g., extended childhood and increased playing behavior); and particularly, reduced levels of reactive aggression (Shea, 1989; Leach, 2003; Somel et al., 2009; Zollikofer and Ponce de León, 2010; Plavcan, 2012; Fukase et al., 2015; Stringer, 2016).

Diverse factors have been hypothesized to trigger HSD, like the rise of co-parenting, the advent of community living, changes in our foraging ecology, climate deterioration, and/or the colonization of new environments (Pisor and Surbeck, 2019; Brooks and Yamamoto, 2021; Spikins et al., 2021). All in all, these factors might have promoted a selection toward less reactive and more prosocial behaviors, thereby instilling in humans

a constellation of physical, behavioral, and cognitive changes characteristic of domestication. Many human-specific traits, like our enhanced social cognition, our increased cooperation, and finally, our advanced technology and sophisticated culture, are the products of domesticate-like adaptation (see Hare, 2017 for an overview). This collective cooperativity that extends beyond familial gene pool does not necessarily equate to domestication, but it quite closely resembles its principal traits.

As it seems to us, HSD presents a good evolutionary framework for linguistic studies, especially for capturing those aspects of languages that are thought to emerge through a cultural mechanism. It is worth remembering that the earliest hominids, who had high levels of reactive aggression, practiced musilanguage rather than “language” and must have cultivated signals similar to animal communication. The latter simply could not support the “duality of patterning” (Hockett, 1960) and combinatoriality. Therefore, the “linguistic” component in musilanguage is harder to see than the “musical” component, although there is evidence that animal communication uses referential as well as motivational information, each coded differently (Manser 2010). Indeed, animal communication comes much closer to human music than to human language due to its dedication to showing the signaller’s affective state (Fitch, 2006). There is some neurophysiological evidence that “full language” must have crystallized later than “full music”, because the acoustic characteristics of primate vocalizations are mainly determined by music-like features that serve as the foundation of verbal acquisition for human infants (Koelsch, 2009).

However, concluding from this that language evolved from music, as argued by Fitch (Fitch, 2010), seems a far stretch. The principal arguments against this scenario were summarized by Tallerman (Tallerman, 2013):

- Phonological systems do not evolve in isolation from semantics, like “bare vocal sounds.” Consonants and vowels are linguistic entities, and phonological expansion derives from a growing vocabulary of words - not the other way around. It is the developing lexical system that brings to life phonological gestures (B. de Boer and Zuidema, 2010; Lindblom, 1998; Studdert-Kennedy, 2011; Zuidema and de Boer, 2009).
- Despite greater similarity to animal vocalizations than human language, human song remains fundamentally different from animal vocalization. Animal-learned

vocalizations lack transposability of intentions (i.e., repeated use of the very same signal in different circumstances) and abstraction of the representation of an affective state, which are the landmarks of musical emotions. A single animal call is the basic unit of animal communication - produced instinctively in response to the actual stimulus present in the environment (Zuberbühler, 2017). And animal-learned vocalizations are limited to display of fitness (Naguib and Riebel, 2014), are season- and gender-specific (Slater, 2011), and relate to mating or territory-defending situations (Slater, 2001) - unlike human music.

- Animal learned vocalizations (some ethologists and researchers of animal communication call them “animal songs”) have a critical period of acquisition, are learned holistically, and take months before an animal can deliver it (Hurford, 2012). In contrast, humans can learn songs at any life-stage, do it incrementally and rather quickly. Evidently, human song-learning engages very different neuro-physiological mechanisms, and constitutes not an extension but a *parallel* evolutionary development to animal song - as Fitch himself recognizes (Fitch 2010, p.184).²¹
- Finally, it is hard to explain how and why music-like aspects of hominin vocalizations would have reduced their musicality and given rise to consonants that are fundamentally “unmusical” and notably absent in animal communication (Kolinsky et al., 2009). The musicality of speech comes from prosody, and prosody comes from joining words into phrases. Musical phrases have nothing in common with linguistic phrases other than the misleading term “phrase” (Benjamin et al., 2015) - linguistic phrases are built around words and their categorical relations, whereas musical phrases are determined primarily by the breathing rate that characterizes different emotional states (greater excitement transpires in shorter phrases) and general release of tension towards the end of a phrase, which accompanies expiration (Alekseyev 1976)²².

²¹ For this reason, the distinction between animal calls and songs has nothing to do with the distinction between human calls (e.g., the genre of forest-calls) and songs. Both distinctions emerged at different times, determined by different factors, and followed different evolutionary trajectories. There was a fundamental reorganization of expressive means in human musical communication in comparison to animal communication, which took place some time during the Paleolithic, resulting in the complete reversal of semantic values for quite a number of acoustic attributes of typical animal vocalizations (see (Nikolsky, 2020b)).

²² Although quite a number of researchers equate musical and linguistic syntax, the parallels between pitch and interval classes and sets, chordal typology, and key structure of music on the one hand and, correspondingly, phonological, morphological, and morphonological organizations of language are limited to only the latest stage of evolution of music, specifically as it is

As we see, the evolutionary continuity of animal communication and human music is quite superficial - human song and animal song constitute independent developments - and there is no reason to trace the origins of language from music. Under closer scrutiny, animal communication combines the semiotic characteristics of both human music *and* language (Manser, 2010):

- Animals use *referential* calls (i.e., they refer to specific attributes of the eliciting external stimuli, so that the receivers of these signals react to these external stimuli) when encountering predators, discovering a food resource, and in agonistic social interactions,
- Animals use *motivational* calls (i.e., such calls display the emotional state of a caller, so that the receivers react to this emotional state) in all other situations. Ontogenetically, acquisition of motivational calls precedes acquisition of referential calls and appears to be simpler in structure.

Musilanguage just inherited referential and motivational specialization from animal communication and advanced it to the next evolutionary stage - building the repertoires of calls of both types and introducing some transposability of their use. In this process, each type obtained a set of characteristic structural features that allowed listeners to distinguish both types upon hearing them. Motivational calls probably resembled the repertory of infantile vocalizations during the first few months of life, categorized into negative cries of various sorts and positive cooing - all characterized by prolonged use, like music (typically, as long as the emotional state lasts).

Referential musilanguage calls likely resembled the earliest attempts of an infant to point to specific things in a dialogic communication with a caretaker with the aid of gestures - shorter and more of turn-taking than the “monologic” motivational vocalizations. Such a “wordless” linguistic component is what Brown outlined in his 2017 amendment of the musilanguage theory with his new “prosodic scaffold” model (Brown, 2017). According to it, musilanguage conveyed primarily affect-related information in two principal ways:

implemented in the Western classical music tradition (see Nikolsky & Benitez-Burraco in press). For majority of known non-Western musical systems that do not subscribe to the principles of Western tonality, similarities between musical and linguistic syntax are confined to the elementary "surface" level of tonal organization - what music theorists qualify as "motivic" rather than "phrasal" level of compositionality.

- through “affective prosody” (music-like) by means of anatomically available and innate impulse-driven modulations of pitch, loudness and tempo - global and holistic for the entirety of a call;
- through “intonational prosody” (speech-like) by filling a prosodic scaffold with phoneme-like deictic utterances - employing both global and local mechanisms for conveying linguistic modality (e.g., question versus statement) and emphasis (stress, prominence, focus).

The speech-like way must have evolved from the music-like way through an ongoing adaptation of the reflex-based vocalizations to the most common environmental situations, reshaped by their chain transmission and natural selection for the most effective patterns of communication under the pressure of time - i.e., to successfully deliver signals as soon as possible, enabling live updates on critical changes in the environment. The demand of urgency probably pushed “intonational prosody” towards language, in contrast to “affective prosody,” focused on caller’s expression rather than keeping listeners “up-to-date.” Supported with hominin’s capacity for accumulation of knowledge, the newly forged intonational patterns were memorized and preserved (in contrast to animal communication), leading to the invention of consonants, formation of syllables, and eventual adoption of basic conventional words for the most common objects²³.

In regards to HSD, musilanguage, proto-music, and proto-language, all fall out of its scope, since currently available data does not indicate the presence of a domesticated phenotype amongst extinct hominins, while the data coming from developmental

²³ It is not a trivial task to explain the brain divergence of processing architectures for music and language. Recently, Dehaene and colleagues (2022) have argued that music and language (but also several other human-distinctive abilities, like mathematics) might depend on parallel circuits endowed with similar computational principles, which they construed as internal languages of thought, akin to computer languages. These languages are claimed to recursively compute small sets of symbols, or primitives, whose nature varies from one domain to another (merge and antisymmetry for language, but pitch and rhythm for music). These mental programs encoding nested repetitions with variations contrast with the simpler computational models that can capture non-human primate data. Interestingly for our concerns here, Dehaene and colleagues have hypothesized that some mutation(s) in the human lineage might have granted compositionality to many, possibly all, human cortical circuits. This circumstance would account for the fact that although these circuits process different types of primitives and differ in their styles (e.g. pitch and rhythm for music; merge and antisymmetry for language; etc.), they exhibit similar computational properties (particularly, the ability to process symbolic items recursively).

psychology and ethnomusicology is applicable to *Homo sapiens* only. Extrapolating our conclusions on the factors at play (see Nikolsky and Benítez-Burraco 2022 for details), it is plausible to expect that hominins who practiced proto-music and proto-language, perhaps even musilanguage, had lower levels of reactive aggression than non-human primates. Some traits established for *Homo erectus* might be interpreted as promoting cooperative behaviors between closely related partners: hunting and gathering in groups, caring for injured and sick group members (Leroy et al., 2011), need for helpers during delivery due to a large cranial size, caretaking assistance due to longer altriciality (Boaz and Ciochon, 2004), and migration to cold Europe, where hardship of survival was likely to encourage mutual support in such activities as communally planned big game hunting, maintaining fire, and making clothes and huts - all suggestive of some form of communication between the participants (Mania and Mania, 2004). However, such arguments remain speculative until more conclusive archaeological evidence is uncovered.

For humans, HSD can account for the evolution of abilities and behaviors that enable the cumulative growth of linguistic complexity through an ongoing multi-generational learning and use. This involves language teaching and practicing, promoted by a more prosocial and neotenic phenotype. In a series of related papers, Benítez-Burraco and Progovac (Progovac and Benítez-Burraco, 2019, Benítez-Burraco and Progovac, 2020, 2021) have developed a detailed model of how HSD might have contributed to the evolution of language (and of languages). At the time of the emergence of early humans, reactive aggression was still high, and consequently, communication through language must have been limited to single-word commands, threats, and exclamations, mostly aimed to convey emotions. Patient and cooperative turn-taking, using long utterances, and conveying referential meanings, frequently observed in present-day interactions, was simply unattainable back then.

Growing HSD supported stronger in-group networks, involving more diverse, frequent, and prolonged contacts between their members. Cooperative turn-taking must have become more common and elaborated, enabling the development of linguistic structures via cultural transmission. It is plausible to expect that single-word utterances were replaced by rudimentary two-slot grammars, made of nouns and verbs to express predications. These earliest grammars might have been primarily used for creating

colorful derogatory expressions (since emotional reactivity was still quite high), contributing to further increase of HSD, as these derogatory utterances helped replace physical reactive aggression by less harmful verbal aggression.

The main reason for the positive feedback loop between reactive aggression and grammar is the functional connection and partial overlap of the brain mechanisms that support combinatoriality and control of reactive aggressivity. To give just one example, in learned aggressive actions (a form of controlled aggression), the prefrontal cortex regulates the activity of the hypothalamus (and component of the ‘core aggression circuit’) and the striatum (part of the ‘learned aggression circuit’) (Lischinsky and Lin 2020). But the striatum plays a key role in grammar processing as part of the procedural memory and more generally, the cortico-subcortical networks responsible for hierarchical processing (Teichmann et al. 2015). Evidence of this functional connection/partial overlap is the concurrence of problems with structural aspects of language and aggressive outbursts in clinical conditions, resulting from striatal dysfunction (Savage 1997; Rosenblatt and Leroi 2000; Zgaljardic et al. 2003). Accordingly, from an evolutionary point of view, one can expect that reduced reactive aggression, resulting from increased HSD, demanded an increased control of subcortical structures by the cortex, which also promoted cross-modality - i.e., the ability to combine information from different cognitive domains - pivotal for merging linguistic items (see Benítez-Burraco and Progovac, 2021 for a more detailed discussion).

Once HSD reached its peak at the end of the Upper Paleolithic (Cieri et al., 2014), behaviors conducive to the advance in linguistic complexity via cultural mechanisms also proliferated (e.g., more frequent and diverse contacts, extended learning periods, and greater opportunity to practice via playing). Such changes likely put in place the first hierarchical grammars that expressed transitivity, and more generally, what has been called *esoteric languages*. These languages typically exhibit larger sound inventories and complex phonotactics, opaque morphologies (with more irregularities and morpho-phonological constraints), limited semantic transparency (abundant idioms and idiosyncratic speech), reduced compositionality, and less sophisticated syntactic devices. These features are common for isolated human groups, living in small, close-knit communities with high proportions of native speakers - a rough proxy of languages spoken by present-day hunter-gatherer societies.

The transition from the Upper Paleolithic to Neolithic was accompanied by cardinal changes in social organization as a result of a steady demographic growth and climatic changes. Growing social interactions brought to life extensive social networks, promoting trading and mating, while also unleashing inter-group hostilities in competition for limited natural resources. The necessity to regulate conflicts, convey de-contextualized meanings, and exchange technological know-hows with non-kin individuals favored the emergence of *exoteric languages*. These languages typically feature expanded vocabularies and increased syntactic complexity (including greater reliance on recursion), as well as greater compositionality and enhanced semantic transparency – all advanced at the cost of simpler phonological inventories and sound combinations, and more regular morphologies. A proxy of such languages are the languages spoken by present-day agriculturalist societies, particularly, state-governed indigenous societies. Since these languages are also suitable for conscious planning, establishing alliances, conducting warfare, and ultimately, supporting the emergence of cultural institutions related to war and peace, their emergence can be linked to the advent of *proactive* aggression that became more widespread during this period.

Our model of evolution of human languages under the effects of HSD can also explain modern uses of language (i.e., modern pragmatics and linguistic modes of interaction). A reduction in reactive aggression is beneficial for cognitive and behavioral changes necessary for the emergence of rules of turn-taking and complex inferential abilities, both of which are cornerstones of our conversational abilities. On the cognitive side, the expansion of pair-bonding to non-reproductive relationships marked a crucial achievement in social organization. The potentiating of cross-modal thinking, instrumental for linguistic chunking, enabled conventions of figurative uses of language (e.g., metaphors and metonyms) and pragmatic inferencing. On the behavioral side, increased HSD favored prolonged face-to-face interactions, long-term cooperation, and consideration for others' needs. Overall, these cognitive and behavioral changes enabled communication of more complex meanings by indirect means (see Benítez-Burraco et al., 2021 for a detailed view).

In general, this HSD model ties the evolution of language with changes in aggression management, both reactive and proactive, ultimately connecting specific linguistic

structural features with the HSD-related behavioral and cognitive changes, based on their shared neurobiological substrate. At the same time, this model establishes a strong continuity between communication and cognitive abilities exhibited by other species, while also supporting cultural niche construction, cultural evolution, and gene-culture coevolution as key factors that accounted for the exclusiveness of language to human communication. Our contention here is that the same model can be also applied to human musicality, music types, and functions of music - not only because of the common origins of music and language, but mostly because of the common effects of changing levels of reactive and proactive aggression.

7. HUMAN SELF-DOMESTICATION AND THE EVOLUTION OF MUSIC

As noted, we find our HSD model of coevolution more parsimonious than those accounts that hypothesize different rationales and mechanisms for the evolution of music and of language. Our approach reconciles hypotheses about music evolution that have been presented as irreconcilable, like the “social bonding hypothesis” (Savage et al., 2020) and “the credible signal hypothesis” (Mehr et al., 2020). Moreover, this model explains better than other models how different types of music diachronically emerged through a cultural mechanism - which was previously examinable mostly through memetic approaches (see Jan, 2018). Overall, we hypothesize that the gradual changes in the subtle balance between reactive and proactive aggression could help understand the steady complexification of music, the emergence of its new functions, and the transformation of the old ones, as well as the past and present distribution of musical types and genres as reported by ethnomusicologists.

Our model is summarized in Figure 2, where music evolution is presented vis-à-vis language evolution to highlight their common origins and their parallel evolutionary pathways under the effects of HSD, changes in paleoclimatic conditions, demographic changes, and relevant cognitive and behavioral innovations. We support the view that the evolution of music systems and languages can be conceived as two different products of the same biological/cultural processes, heavily influenced by the increased feedback loop between the reduction of reactive aggression and the sophistication of language and music structures and uses.

In brief, once a musilanguage emerged from the building blocks rooted in animal communication, cognition, and behavior, proto-music started to diverge from proto-language, later evolving into timbre-based music, and thereafter, into pitch-based music, ultimately generating collective forms of music that can be found in many present-day societies. Still, these stages should not be viewed as a clear-cut “monolithic” order of things. Since environmental and social conditions instrumental for HSD are always in the process of transformation, HSD levels are prone to vary from one place to another, and from one human group to another (see e.g. Glesson and Kushnick, 2018 for sexual dimorphism under the HSD effects). Therefore, we expect significant historic and geographic overlaps between different evolutionary musical types globally. As the available ethnomusicological data suggests, the schemes of tonal organization that characterize different stages of evolution of musical structures tend to build on top of each other, retaining the previous formations. Even in music cultures of modern Western countries that are based on full-fledged tonality (the conventional key system of Western classical music tradition), it is often possible to identify traces of the older methods of tonal organization (musical modes, including those that feature less than 7 pitch-classes) that usually survive in specific folk genres (most commonly, within the venerated epic and religious traditions).

It would be unrealistic to expect that each stage in our model started at the same time worldwide. This is in line with current evidence of modern human behavior appearing in different regions at different points of time (Ashton and Davis, 2021). We reserve the possibility that other close hominins, particularly, Neanderthals and Denisovans, will fit in the first stages of our model, if evidence of their human-like management of reactive aggression emerges. Below, we provide a more detailed description of our model.

Figure 2. The timeline of the co-evolution of music and language. The figure reflects the evolution of types of music vis-à-vis the evolution of types of languages in regard to the changes in human socialization patterns under the effects of increased HSD (reproduced from Nikolsky and Benítez-Burraco, in press, figure 7).

8. THE SUMMARY OF OUR 4-STAGE MODEL

Before the advent of our species, roughly 300 thousand years ago (kya)²⁴, a musilanguage stage can be hypothesized for the hominin clade. The likely distinction between animal communication and this pre-human musilanguage was the presence of conventional acoustic forms of expression for conveying common emotional and deictic information between the members of the same social group (e.g., loud collective signals to fend off

²⁴ Here and onward, the dates we mention are approximate. There is still a great controversy around the exact timing of the emergence of the human species, but also about the mode of emergence (one single place or multiregional) and the abruptness or graduality of the process, particularly if one considers the extensive admixture with other hominins species (see Neubauer et al., 2018; Scerri et al., 2019; or Meneganzin and Bernardi, 2023, among many others, for interesting discussions).

dangerous predators, or individual grunting patterns to accompany caretaking activities, etc.). Such signals were probably not coordinated in pitch and time between multiple participants, featuring a jumbled “isophonic” texture (Nikolsky, 2018) – very much like howling of a wolf-pack. But unlike animal communication, musilanguage signals can be hypothesized to be intentionally directed at specific group members, to vary in sonic patterns based on application, and be passed on from one generation to another (see Nikolsky, 2020). Such a communication system that enhanced sociality and altruistic behavior must have been critical in promoting cooperation at times of environmental stresses, so frequent throughout the Paleolithic. It is plausible that waves of mass hominin migration from Africa were enabled by the pro-social influence of the musical component in a musilanguage system.

Stage 1 in our model (*proto-music*) starts with the emergence of archaic anatomically-modern humans (AMHs), endowed with cognitive innovations - particularly, with a new neuronal workspace that entailed greater connectivity between distant brain regions and could overcome the limits of core knowledge systems, attaining basic forms of cross-modal thinking (Boeckx and Benítez-Burraco, 2014). Two innovations distinguish proto-music from both musilanguage and proto-language. The first of them – emergence of singing - was a likely outcome of an attempt to maximize the intensity of phonation in distant calls (Maclarnon and Hewitt, 2004) and in collective vocalizations designed to scare off predators or to ambush prey (Jordania, 2011; Jordania, 2017). The second - the accidentally discovered sounds of flinting - probably gave birth to the world’s earliest musical instrument - a couple of rocks hitting against each other in the manner of modern claves (Montagu, 2004). Rhythmic knapping is known to be a natural byproduct of entrainment during collective manufacturing of stone tools (Zubrow and Blake, 2006). The latter was definitely used in prehistoric times (Boivin et al., 2007), and still survives in aboriginal societies in performance rituals, where it is ascribed magic properties (Duncan-Kemp 1952).

Within this stage, some interaction between proto-music and proto-language was likely to have occurred. Consider the case of lullabies and motherese, both of which can be related to our prolonged (in comparison to other primates) altriciality period and shortening of interbirth intervals that posed the need for collective caretaking of multiple children. It is quite possible that specific musical intonations that globally characterize

lullabies (e.g., the descending leaps by about 300 cents – Fernald, 1992; Reigado et al., 2011) might have been cultivated within the motherese throughout millennia of its application. Because we still lack precise knowledge of cognitive and behavioral features of earlier hominins (including their social life), we cannot rule out the possibility that Neanderthals (and, perhaps, Denisovans) also exhibited some sort of proto-music, since they have been hypothesized to share with humans the basic capacity to sing (Mithen, 2005), and to have had some form of culture, particularly symbolic behavior (Mellars, 1996; D’Errico et al., 2003).

Around 200 kya, the long Riss Glaciation started, and climatic conditions became harsher. Frequent alternations of extreme cooling and warming caused significant fluctuations in sizes of social groups. Depopulation periods increased the value of cooperation in harsh environments, strengthening bonds and stimulating interpersonal communication. During subsequent periods of demographic growth, newly established patterns of communication were cultivated over larger territories and involved a greater number of people. The seesaw demographic alternations favored selection for increased prosociality and promoted personal and inter-personal uses of proto-musical behaviors.

Two formats - solitary musicking to entertain oneself during prolonged solitary activities (the babbling model) and duetting of closely related persons (the motherese model) during the depopulation times - provided a fertile ground for the invention of “musical mode.” Bonded couples intuitively matched the sonic characteristics of their vocalizations, and solitary musicking gave an opportunity to explore the combinatorial capacities of the matched common patterns of expression. The resulting set of sounds that pleased the sensibilities of music-makers was thereafter conserved for future musicking. Tone-matching probably originated from mother-infant interaction, characterized by instinctive mutual imitation of the expressive vocal attributes (Malloch and Trevarthen, 2009) and fueled by oxytocin (Harvey 2020). Much of this mimicking is confined to the domain of timbre, which makes it the most likely substrate for the earliest musical modes. A set of timbre-classes, selected and repeatedly used to express specific semantic contents, constitutes what can be called a “musical timbral mode” (Nikolsky et al., 2020), which is the type of music we hypothesize for Stage 2 in our model.

The “natural” (anatomy-driven) rules of binding acoustic properties with emotional semantic content, typical for animal vocal communication, were ultimately replaced by “cultural” conventions that often violated “natural” order of things (as it is characteristic for present-day human music). Here, particularly instrumental must have been the peculiar institute of “*personal song*” (Nikolsky et al, 2020). In numerous music cultures of indigenous hunter-gatherers of the Extreme North, whose lifestyle comes the closest to that of early humans during the Quaternary Glaciation, every person is assigned a personal song that indicates one’s place of origins, ethnicity, kin, age, occupation, and temper (Nikolsky et al., 2020; Sheikin, 2002). Personal song is crucial for avoidance of incest in marriages in scarcely populated areas. Its honest use is protected by a widespread Ancestor Cult and by social conventions imperative for one’s survival in harsh environments.

All in all, personal song presents a likely model for a transitory stage between the animal-like proto-music and the full-fledged human music. Personal song resembles animal songs in marking territoriality and ancestrality, while assisting mating (see Bradbury and Vehrencamp, 2011). But in sharp contrast to instinct-driven animal songs, parents actually “compose” personal songs for their newborns - they deliberately use tone-classes (entailing timbre, rhythm-meter, and pitch contours) to represent the child’s temper. Ultimately, the fact of coexistence of personal song and timbre-oriented music tradition amongst numerous ethnicities of Siberia and Russian Far East, as well as the inherent spatial limitation of timbral music (timbral modulations are practically inaudible beyond the distance of a few meters) make a timbre-oriented personal song a very likely candidate for the forms of music characterizing our Stage 2. The development of personal song is directly related to the ongoing reduction in reactive aggression, since the circulation domain of one’s personal song is primarily one’s extended family within the kin, characterized by greater tolerance in comparison to the outsiders. Also, the ongoing everyday musicking by every individual owner of a personal song was likely to promote greater emotional control, thereby contributing to the general reduction of interpersonal conflicts within a community. The evidence of such a mediative and regulatory role of music has been provided by numerous recent studies of the enhancing influence of music on the inhibitory control in children (Moreno and Farzan, 2015; Joret et al. 2017; Hennessy et al., 2019; Bolduc et al., 2021; Bugos et al., 2022).

Around 110 kya, the Riss-Würm Interglacial period came to its end, and the climate deteriorated again, bringing the Last Glaciation that lasted until 10 kya. This period, when HSD reached its peak (Cieri et al., 2014), and the evidence of behavioral modernity was revealed in most parts of the world, we see as Stage 3 in our model. For music, the primary achievement towards the end of this stage was the emergence of cross-cultural pitch orientation, evident in the uncovering of over a hundred of “bone flutes” in caves, often in bundles, all over a wide region from Germany to Spain, dated 36-30 kya (Morley, 2013). Similarities in their construction (D’Errico et al., 2003) suggest the ongoing cultural interaction throughout 45-30 kya along the Danube Corridor (Higham et al., 2012).

The rise of pitch orientation can be attributed to several factors. During 110-10 kya, caves with fire became common for living (Kempe, 1988). Cave reverberation is distortive for timbre-classes but resonant for pitch-classes (e.g., it makes familiar voices unrecognizable but amplifies a pitch value). Reflections from the walls make pitch changes more salient due to the prolonged decay of each sustained pitch level. Inhabitant Paleolithic caves usually resonate at a specific frequency, about 110 Hz (Devereux, 2006), and contain stalactites usable as lithophones - in some caves they produce sophisticated scales (Dams, 1985). Both resonance and lithophones might have provided the reference pitch for singing. The most resonant locations in such caves often contain paintings, dated from 35 kya onwards (Díaz and García, 2012). The same affiliation characterizes “sounding rocks”, some of which contain marks of hitting, indicative of their ritual musical usage (Morley, 2013). Most Paleolithic “bone flutes” were uncovered in caves (ibid.), testifying to the pitch orientation of European Paleolithic music.

Another pitch-inducing factor is the intuitive tuning-in that occurs, when numerous singers try to sing the same melody: they tend to resolve sustained inharmonious combinations of tones (Zarate et al., 2010) into harmonically “perfect” intervals of unison, octave, 5th and 4th (Tallmadge, 1984). All things considered, cave-singing had powers to direct singers’ attention to the fundamental frequency and harmonicity, while promoting uniformity in pitch changes. Together with the above-mentioned tendency of chain-transmission to discretize pitch, these conditions were likely to convert earlier timbral modes into pitch-sets. In turn, the self-domestication features promoted extensive prosociality, favorable for communal cave-living and collective use of music.

The advent of the Holocene marks the final stage in our model, roughly 10 kya, when population growth resulted in prolonged inter-group contacts, extensive social networks for trade and intermarriage, and in many cases, escalated conflicts between larger human groups. A new type of aggression - proactive - became more frequent. All these promoted a new type of music that entailed standardized intervallic typologies and tuning, as well as prescriptive rules for combining pitch-classes. Standardization of pitch- and interval-classes and sets inevitably reduces the diversity of musical modes, instituting formal music training and introducing the notion of musical error (Nikolsky, 2016a). Music becomes professionalized and regulated by political or religious authorities. This transformation of a rather free and loose usage of great multitude of musical modes in all-inclusive folk family- and village-musicking into a restrictive “correct” implementation of just a handful of musical keys, often supported by some sort of musical notation, has been documented in the ancient Babylonian (Dumbrill, 2005) and Greek music systems (West, 1992).

Standardization of keys boosted the development of orchestral and choral music, invention of instrumental families, and the genesis of cyclic music forms that contained contrasting movements – i.e., complexities that were inaccessible before the standardization (Nikolsky, 2016b). Music, performed and auditioned *en masse* in service of the state or/and religion, became a political weapon in hostilities between countries, consolidating citizens across kins, clans, and casts, against the supposed negative influence of neighboring cultures. Political use of music and language, where language consolidates communities by conveying ideas and arguments in their support, while music backs the language by instilling the appropriate emotional states, has only culminated towards the 20th century, comprising official propaganda in the majority of world’s countries. For this reason, we periodize this fourth stage as continuing until the present.

9. CONCLUSION

In this paper, we have outlined our new model of coevolution of music and language under the influence of aggression management throughout human evolution. Enabled by the reduction in reactive aggression - due to a number of paleo-environmental factors - music and language started as undifferentiated forms of emotional and referential

signaling within musilanguage. Initially, they abided by the principles of animal communication: relying on the single-signal "monologic" display of the signaler's affective state and the deictic reference to something observable to the signaler. Growing control of aggression within the basic family units promoted development and inter-generational transmission of patterns of communication, eventually forming two autonomous systems. Proto-music specialized in regulating the emotional states of individuals in their solitary activities and everyday interactions. Proto-language specialized in timely delivery of referential information (including live streaming) and directed and coordinated important collective activities. Capacity of music to promote empathy and bonding favored the formation and transmission of lexical and grammatical conventions instrumental for the complexification of language. Crystallization of musical timbral modes marked the bifurcation of music and speech.

- Music focused on the aesthetic appreciation of sonic attributes, evolving towards the selection of holistic idiomatic patterns whose acoustic properties were suitable for evoking specific emotional states common to a given lifestyle.
- Language focused on effective encoding of important referential information, evolving towards the selection of contrasting easy-to-process phonemes, the combination of which could supply enough words to refer to the surrounding objects and frequently occurring events.

Hence, language headed towards symbolic semiosis, driven by the need to quickly update information, in contrast to music heading to iconic semiosis, supporting the need to secure emotional contagion by means of prolonged exposure to a musical emotion.

Increased cooperation and social interaction favored the emergence of pitch-oriented music, which became effective at long-distance communication to a large number of people. Subsequently, it turned into a tool of social mediation, forging formats of collective performance that distinguished it from language even more. Speakers took turns, whereas singers sang together. At this point, music counter-balanced language along the opposition of "me" versus "us". Language supported individual awareness, bringing to light differences between individual interlocutors, while music carried the opposite effect of emphasizing what was in common between multiple performers. In the long run, language promoted individualization and analysis, offset by music that promoted integration and synthesis. Their antithesis and mutual compensation further intensified as music and language reached their exoteric stages. Music became the means

of inspiring masses to feel a certain way (most commonly, patriotic, family-related, and religious), whereas language became the instrument of reasoning, frequently counterposed to “feelings”. Music and language developed an antinomy of “heart” versus “mind”. Their dichotomy still fuels our cultural life today.

Overall, we have argued for a gradual co-evolution of different types of music and of languages as the structure of human groups became more complex and diversified as a result of changing the balance between reactive and proactive aggression. If early stages in the evolution of music and language were characterized by the curbing of reactive aggression, later stages became associated with the rise of proactive aggression. Our model provides a unified view of the evolution of language and music under the effects of changes in human cognition and behavior, which can and should be tested by subsequent studies.
